Values are means ± SD. Q = blood flow; DO_2 = oxygen delivery; both are expressed as milliliters per minute per 100 gm, except for uterus plus placenta, expressed per kilogram of uterus plus placenta plus fetus. Note that liver blood flow is the sum of hepatic arterial and portal venous blood flows; portal blood flow is the sum of the arterial blood flows to all gastrointestinal tract organs. Without data on portal venous blood oxygen concentration, total liver oxygen delivery could not be calculated.

*$p < 0.05$, analysis of variance.

creased to 15% and then began to decrease when maternal hematocrit was reduced below about 15% (Table III and Fig. 4, *A*). Systemic oxygen delivery decreased gradually as hematocrit was reduced from 31% to 15% but fell more rapidly at lower hematocrits (Fig. 4, *B*). As compensation for the fall in systemic oxygen delivery, oxygen extraction increased (Fig. 5, *A*) so that systemic oxygen consumption could be maintained over the range of maternal hematocrits from 31% to about 15% (Fig. 5, *B*). At hematocrits ≤15%, systemic oxygen consumption began to decrease. The decrease in oxygen consumption at hematocrits ≤10% was associated with a combined metabolic acidemia (reduced arterial blood base excess) and a respiratory alkalemia (reduced arterial blood P_{CO_2}) (Table I).

Comment

Oxygen delivery to tissues is a function of two variables, the tissue blood flow and the arterial blood oxygen concentration.[1-4] At normal hematocrits blood flow is primarily determined by the cross-sectional area of the vasculature and by the perfusion pressure.[3] When hematocrit is altered, however, the attendant changes in blood viscosity also directly influence tissue perfusion. Because the relative contributions of vascular geometry and viscosity to blood flow regulation differ from one vascular bed to another,[3-5] the effect of anemia on blood flow and oxygen delivery to tissues shows regional variations. In our experiments on pregnant sheep, we identified three general patterns of response of regional blood flows and oxygen deliveries as func-

tions of maternal hematocrit during acutely induced anemia.

In the first pattern of response, seen in the heart, brain, and adrenal glands, blood flow varied inversely with hematocrit so that oxygen delivery to these organs was held constant or decreased modestly over about a fourfold range of hematocrits (8% to 31%) and a fourfold range of arterial blood oxygen concentrations (3.9 to 14.6 ml of oxygen per deciliter of blood). A portion of the increase in blood flow was probably due to the rheologic effects of reduced blood viscosity that occur during anemia.[4, 5] This increase by itself, however, would not account fully for the large increases in organ perfusion that we observed.[3, 5] Since perfusion pressure did not change during acutely induced anemia, some of the rise in blood flow in the heart, brain, and adrenals must have been due to vasodilation. In the heart of the pregnant sheep, the combination of decreased viscosity and coronary vasodilation produced sufficient increases in perfusion for coronary oxygen delivery to be unaffected by the degrees of acute maternal anemia produced. In contrast, in the brain and adrenal glands, blood flow increased to a lesser extent than that required for maintenance of oxygen delivery. Thus oxygen delivery decreased slightly as maternal hematocrit was reduced. Our observations on the responses of the heart, brain, and adrenals to acute anemia in pregnant animals are similar to those made in nonpregnant adult animals[3] and in fetal[1] and neonatal[2] animals, indicating that the coronary, cerebral, and adrenal circulatory responses to anemia are qualitatively the same at all stages of development.

In the second pattern of response to acute maternal anemia, blood flow showed no net effect as hematocrit was reduced. Since the effects of viscosity, at any given shear rate, are uniform throughout all vascular beds,[3-5] perfusion should have increased as viscosity was reduced. The lack of an increase in blood flow to the kidneys, the splanchnic organs, and the uterus-placenta suggests that these circulations were vasoconstricted during maternal anemia. This latter interpretation may appear to be unsupported by our data, since we showed that vascular resistance, calculated as mean arterial blood pressure divided by blood flow, did not change in these organs. However, a constant resistance indicates the lack of either vasoconstriction or vasodilation only when hematocrit and thus viscosity are also constant.[3] When hematocrit and viscosity vary, vascular resistance must be considered to be primarily a function of two components,[3] the blood viscosity and the cross-sectional area of the vasculature, as follows: $R = 8\eta l/\pi r^4$, where R = resistance, η = viscosity, l = length of the vascular channel, and r = radius of the vascular channel (a measure of the cross-sectional area). A decrease in viscosity, η, due to anemia would be expected to lead to a reduction in resistance, R. Our data, however, indicated no such reduction. Therefore the radius, r, of the vascular channel must also have decreased as a result of vasoconstriction (the length of the vascular channel, l, is fixed anatomically and would not be expected to vary during anemia).

The splanchnic, renal, and uterine vascular beds vasoconstrict in response to a variety of stresses[12, 13] that are associated with sympathetic nerve stimulation or

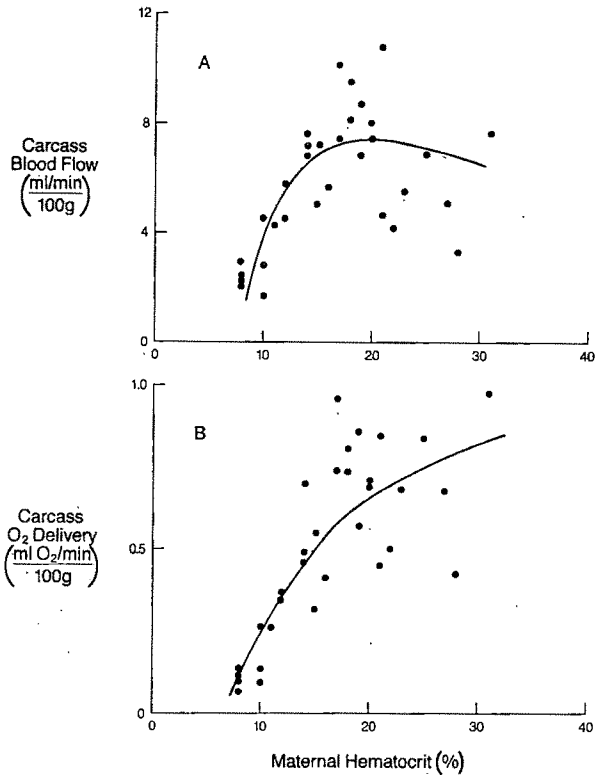

Fig. 3. Third pattern of response to acute maternal anemia. catecholamine release. Acute anemia may also produce vasoconstriction that is mediated neurohumorally. Since perfusion to the kidneys, splanchnic organs, and uterus did not vary during maternal anemia, oxygen delivery to these organs was directly dependent on hematocrit. Despite such a dependence, the quantity of oxygen utilized by these organs must have been maintained as hematocrits were lowered to about 15%, since systemic and uteroplacental oxygen consumptions[8] were unaffected by decreases in maternal hematocrit to similar levels. At hematocrits ≤10%, the oxygen supply to these tissues must have been inadequate for aerobic metabolism, judging by the reduction in systemic and uteroplacental[8] oxygen consumptions that developed.

In the third pattern of response to maternal anemia, seen in the carcass tissues, blood flow increased as hematocrit was decreased to about 15% and then dropped rapidly as hematocrit was reduced to lower levels. The initial rise in carcass perfusion could be accounted for entirely by decreases in blood viscosity,[5] in the absence of any active vasoregulation. However, when hematocrits were reduced to less than about 15%, the decrease in perfusion we observed must have been due to substantial degrees of vasoconstriction in carcass tissues, which outweighed the beneficial effects of further reductions in viscosity on tissue perfusion.[3, 4] As with the kidneys, splanchnic organs, and uterus, vasoconstriction in carcass tissues was probably a result of enhanced sympathetic nerve activity or catecholamine secretion.[12] Although vasoconstriction was present to some extent in organs and tissues exhibiting both the second and third patterns of response, its effects were more pronounced in the tissues of the carcass than in those of the abdominal viscera.

The changes we observed in cardiac output and systemic oxygen delivery as functions of maternal hematocrit were the summation of all the individual organ

and tissue responses to maternal anemia. Cardiac output increased as hematocrit was reduced to about 15%, because blood flow to the heart, brain, adrenal glands, and carcass tissues increased. Cefalo et al.,[14] however, found that isovolemic anemia, when initiated rapidly (<1 hour), did not produce an increase in cardiac output in anesthetized sheep, even though systemic vascular resistance fell. Differences in experimental design between their study and ours may explain the differing responses of cardiac output to acute anemia. In our experiments, when hematocrits were dropped below about 15%, cardiac output fell to values seen when hematocrits were ≥26%, because the continued increases in perfusion to the heart, brain, and adrenals were offset by progressive decreases in carcass blood flow.

Although cardiac output increased during reductions in hematocrit of up to 50% below normal levels, the increases were less than the associated decreases in arterial blood oxygen concentration, and thus systemic oxygen delivery fell. Despite the fall in total oxygen delivery, systemic oxygen consumption was unaffected by acute variations in hematocrit over the range of hematocrits from 31% to about 15%, because systemic oxygen extraction increased sufficiently as compensation. Similar responses have been observed in nonpregnant adult animals.[15] At lower hematocrits, systemic oxygen consumption began to decline in association with the development of a metabolic acidemia (decrease in arterial blood base excess) and a respiratory alkalemia (decrease in arterial blood P_{CO_2}). The metabolic acidemia suggests that oxygen delivery to some tissues, most likely those of the carcass, was insufficient for oxidative metabolic demands. The respiratory alkalemia was due to hyperventilation that could have resulted from three possible mechanisms[16]: (1) Lactacidemia resulting from anaerobic metabolism is a potent stimulus for ventilation; (2) anemia directly increases chemoreceptor activity and augments respiration; (3) increased sympathetic nerve activity stimulates chemoreceptors, which in turn enhance ventilation.

The level of maternal hematocrit associated with a fall in systemic oxygen consumption and the development of a metabolic acidemia (anaerobic metabolism) was about the same as that which led to anaerobic metabolism in the fetus.[8] This observation might suggest that the maternal organism is not necessarily protected from the adverse effects of anemia at the expense of the well-being of the conceptus. However, if fetal anaerobic metabolism were to develop during severe degrees of maternal anemia and if the anemia were not corrected promptly, fetal death would ensue. After the fetus died, uteroplacental perfusion would fall. The portion of maternal cardiac output designated for uteroplacental tissues would then be available to other maternal tissues whose perfusions and oxygen supplies might have been inadequate for oxidative metabolism. In this way a severely anemic mother could survive, even if her fetus could not. Our current data cannot and should not be extrapolated to encompass chronic degrees of anemia in animal or human pregnancies. It is unknown how chronic anemia might affect the maternal systemic circulation, although in nonpregnant animals acute anemia and chronic anemia produce similar adjustments in cardiac output and oxidative metabolic rate.[17]

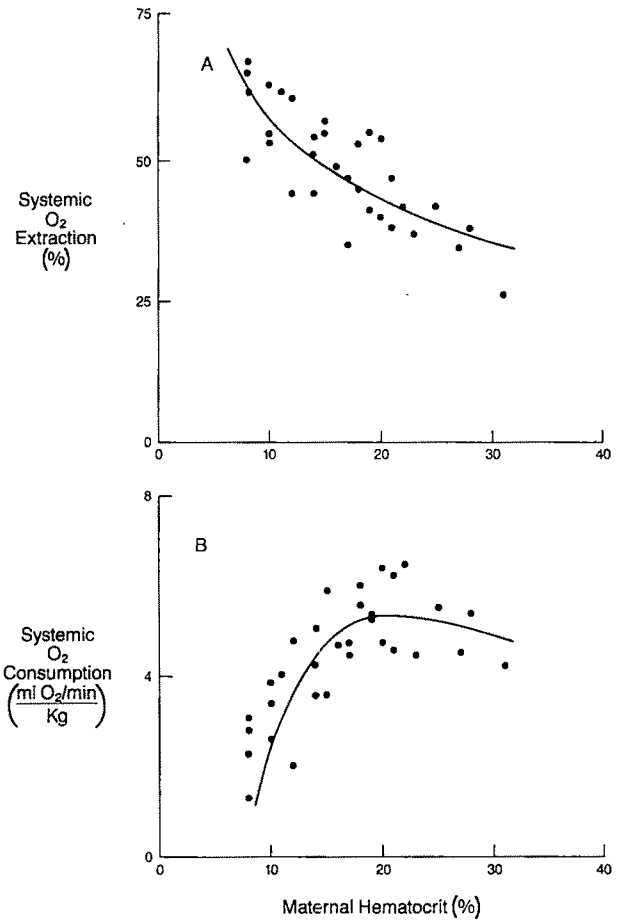

Fig. 5. Systemic oxygen extraction and oxygen consumption (per kilogram of sheep) as functions of maternal hematocrit. *A*, Oxygen extraction versus hematocrit, $y = 159x^{-0.44}$; $r = 0.82$, $p < 0.001$. *B*, Oxygen consumption versus hematocrit, $y = (114 \ln x - 236)/x$; $r = 0.83$, $p < 0.001$.

In summary our data indicate that the organs and tissues of the pregnant sheep show regional variations in their responses to acute isovolemic anemia. Blood flows to the heart, brain, and adrenal glands increase as compensation for reductions in hematocrit. Oxygen delivery to those organs is affected little by reductions in hematocrit and thus in arterial blood oxygen con-

centration. In all other organs and tissues, blood flows either are affected modestly or are reduced during anemia, with the result that oxygen delivery to these latter tissues decreases as a function of maternal hematocrit. Despite reductions in oxygen delivery to many tissues, systemic oxidative metabolism can be sustained at normal levels even when hematocrit is reduced by as much as 50% below normal levels. The responses observed in pregnant animals are qualitatively similar to those noted for nonpregnant animals and for fetal and neonatal animals, indicating that the pattern of the cardiovascular response to acute anemia is the same throughout all stages of development.

We wish to thank Anthony Battelli, Pat Moran, and Lynn Heckman for their excellent technical assistance.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Myocardial adenylate cyclase activity in ritodrine-treated pregnant rabbits

Christos G. Hatjis, M.D., and J. D. Bottoms, B.S.
Winston-Salem, North Carolina

To determine whether prolonged exposure to ritodrine results in down-regulation of myocardial adenylate cyclase activity during pregnancy, New Zealand White rabbits with time-dated pregnancies were randomly assigned to a sham-operated control group and to a ritodrine-treated group. Starting at 22 days' gestation (term 31 days), animals received either intravenous ritodrine intermittently or the equivalent volume of vehicle for 3 days. Adenylate cyclase activity was determined in a plasma membrane fraction obtained from ventricular tissue. There was no difference in the basal activity or the basal and guanosine triphosphate activity between the two groups. L-Isoproterenol–dependent stimulation required the presence of guanosine triphosphate. Both maximal and 50% enzymatic stimulation were equivalent in both groups. Furthermore, sodium fluoride–dependent stimulation was similar in both groups. Finally, adenylate cyclase activity in the presence of forskolin and manganese chloride was similar in both groups. From the above, we conclude that intermittent systemic infusions of ritodrine to pregnant rabbits did not result in down-regulation of myocardial adenylate cyclase activity. (AM J OBSTET GYNECOL 1987;156:749-54.)

Key words: Ritodrine, adenylate cyclase activity, adult rabbit myocardium, desensitization

The stimulating actions of catecholamines on cardiac tissue are primarily, but not exclusively, mediated via β-adrenergic receptors. These in turn regulate contractile and chronotropic responses to stimuli through adenylate cyclase. This enzyme catalyzes the synthesis of 3′,5′-cyclic adenosine monophosphate (3′,5′-cAMP), which acts as a second messenger.[1]

The β-adrenergic receptor–adenylate cyclase complex is thought to consist of at least three protein components: β-adrenergic receptor, stimulatory guanosine triphosphate–binding protein (G_s protein), and adenylate cyclase catalytic activity.[2] When β-adrenergic receptor agonists bind to the β-adrenergic receptor, they promote the formation of high-affinity complex ("ternary" complex of the receptor) with the G-binding protein. In the presence of guanosine triphosphate, the agonists and the β-adrenergic receptor dissociate from the activated G-binding protein, which in turn is thought to interact with a catalytic moiety of the enzyme that leads to adenylate cyclase activation and intracellular 3′,5′-cAMP formation.

β-Adrenergic receptor–adenylate cyclase activities are modulated through two major classes of regulatory mechanisms, homologous or heterologous.[3] In the former instance, the regulator is a hormone that normally binds to the β-adrenergic receptor (β-adrenergic receptor agonist or antagonist). Generally, exposure to an agonist may induce a down-regulation (tachyphylaxis) of β-adrenergic receptor–adenylate cyclase function while an antagonist induces an up-regulation. In the latter case, hormones that normally do not bind to β-adrenergic receptors appear to regulate their function indirectly (thyroid hormones, sex steroid hormones, glucocorticoids). Up- or down-regulation may then be induced. Although the exact molecular stoichiometry of these alterations has not been worked out in all systems, there are at least two ways through which the β-adrenergic receptor–adenylate cyclase complex can be modulated: First, the concentration of β-adrenergic receptors in plasma membranes may be dynamically altered; second, the interaction between the β-adrenergic receptor and the G-binding protein might be changed under certain situations, which would in turn be reflected by changes in adenylate cyclase activity.[3, 4]

Ritodrine, a selective β_2-adrenergic receptor agonist, has been widely used for the treatment of premature labor.[5] It has been shown that this drug may have a wide spectrum of cardiovascular side effects ranging from maternal and fetal tachycardia to electrocardiographic changes and congestive heart failure. Some of these cardiovascular effects are mediated through myocardial β-adrenergic receptor function and adenylate

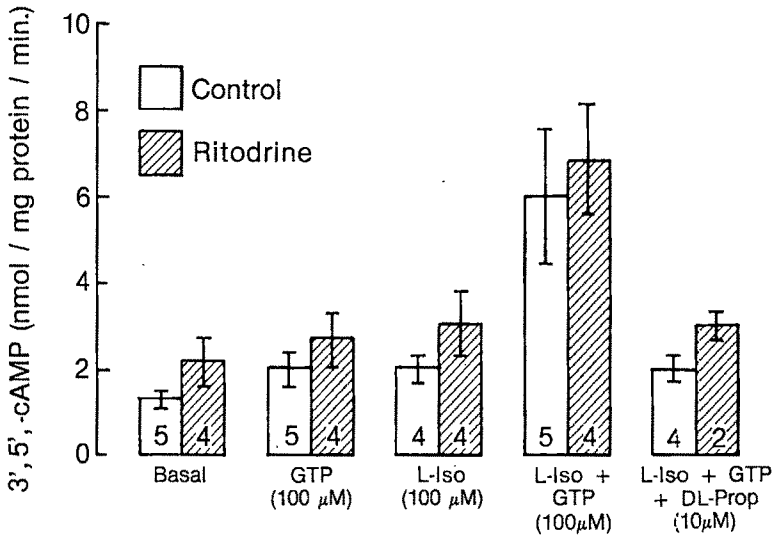

Fig. 1. Basal and stimulated β-adrenergic receptor–dependent myocardial adenylate cyclase activity. *Numbers* in *bars* represent number of individual animals used for that determination. *GTP* = Guanosine triphosphate; *L-Iso* = L-isoproterenol; *DL-Prop* = DL-propranolol.

cyclase activity. Thus it is conceivable that prolonged exposure to ritodrine might result in down-regulation of myocardial β-adrenergic receptor function and adenylate cyclase activity. In this series of experiments we have tried to answer the question whether intermittent administration of ritodrine to pregnant rabbits results in a decrease in myocardial adenylate cyclase activity.

Material and methods

Animals. New Zealand White rabbits with time-dated pregnancies were obtained from a local supplier and housed in our vivarium. At 22 days' gestation (term 31 days) the animals were anesthetized with intramuscular injections of ketamine (30 mg/kg) and xylazine (6 mg/kg). The right jugular vein was then exposed and catheterized with polyvinyl chloride catheters. The catheters were kept patent with infusion of dilute heparin solution in normal saline. The day after operation the animals were randomized into two groups. Group 1, the ritodrine-treated group, received intravenous ritodrine at 7:00 to 8:00 AM and 3:00 to 4:00 PM daily for 3 days. Group 2, the control group, received an equal volume of drug vehicle only (10^{-3}N hydrochloric acid, 0.17 mol/L ethylenediaminetetraacetic acid) according to the same time schedule. At 26 days' gestation, the animals were anesthetized with intravenous pentobarbital sodium (40 mg/kg), following which the doe was put to death. The heart of the animal was then removed in its entirety and separated into ventricles and atria. The position of the jugular catheter was confirmed in the vicinity of the right atrium in all cases. The tissue was then immersed in liquid nitrogen and stored at −70° C until it was used.

The dose of ritodrine received was 5.6 mg/kg of body weight, twice a day. This approximates an average intravenous daily dose of ritodrine for humans (200 μg/min) and represents 1/12 of the 50% lethal dose for rabbits. None of the animals used in these experiments aborted before 27 days' gestation. They were confirmed to be pregnant at the time they were put to death.

Material. Drug and reagents were obtained from commercial sources and were of reagent grade. Ritodrine hydrochloride was provided by Astra Pharmaceuticals. α-^{32}P–labeled adenosine triphosphate (ATP) (10 to 30 Ci/mmol) and 3',8'-^{3}H–labeled 3',5'-cAMP (15 Ci/mmol) were obtained from ICN.

Preparation of heart homogenates.[6] On the day of the assay, the heart ventricle was placed in five to 10 volumes per gram of wet weight of ice-cold 0.9% sodium chloride (w/v) and 20 mmol/L Tris hydrochloride, pH 7.5 (buffer A). It was then minced with scissors and homogenized with a Brinkman Polytron (setting 6-7, 10 seconds). A crude membrane preparation was obtained after centrifugation at 20,000 × g for 10 minutes (4° C). The pellets were then resuspended in 2 ml of ice-cold buffer A and preincubated for 15 minutes at 30° C in the presence of 0.5 mmol/L dithiothreitol, 0.17 mmol/L ethyleneglycol-*bis* (β-aminoethyl ether)-N,N'tetraacetic acid (EGTA), 1 mmol/L hydrochloric acid, 0.2% bovine serum albumin, 5 mmol/L magnesium chloride, pH 7.45. The suspension was then recentrifuged as previously outlined. The resulting pellet was resuspended in ice-cold buffer A (100 to 150 volumes per gram of wet weight) and used in the assay.

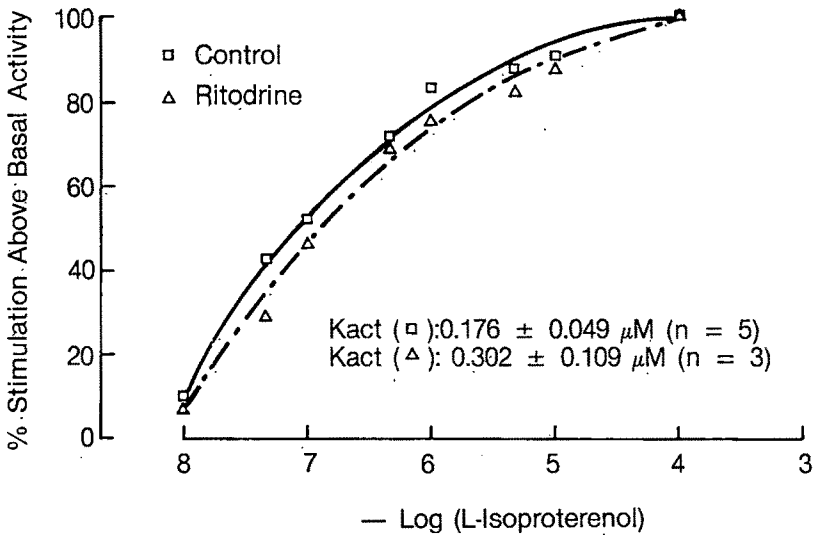

Fig. 2. Dose-response curves for L-isoproterenol–stimulated myocardial adenylate cyclase activity in pregnant adult rabbits. Each point represents the mean of three to five individual determinations.

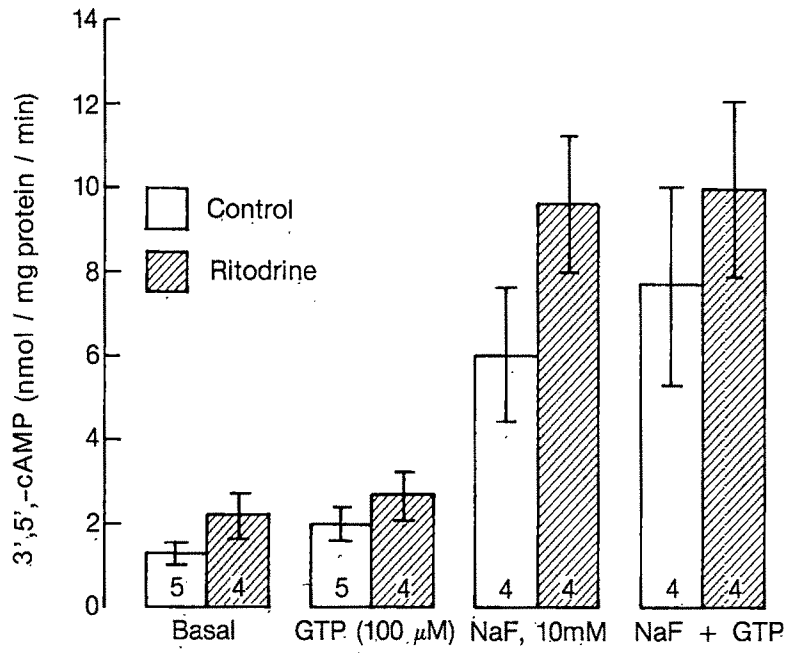

Fig. 3. Basal and stimulated sodium fluoride *(NaF)*–dependent myocardial adenylate cyclase activity. *Numbers* in *bars* represent number of individual animals used for that determination. *GTP* = Guanosine triphosphate.

Adenylate cyclase assay. Adenylate cyclase activity was determined by measuring the conversion of α-^{32}P–labeled ATP to ^{32}P-labeled 3′,5′-cAMP and isolating the product by a modification[6] of a method developed by Salomon.[7] The reaction was carried out in duplicate or triplicate at 30° C for 10 minutes in a final volume of 0.2 ml containing 0.1 ml of membrane fraction (0.23 to 1.3 mg of protein per milliliter) and 50 mmol/L Tris hydrochloric acid, pH 7.5, 0.45% sodium chloride, 0.5 mmol/L adenosine triphosphate, 5 mmol/L magnesium chloride, 0.17 mmol/L EGTA, 0.05 mmol/L 3′,5′-cAMP, 0.5 mmol/L dithiothreitol, 0.75 mmol/L 3-isobutylmethylxanthine, 0.1 mg/ml creatine kinase, 10 mmol/L creatine phosphate, and 1 to 2 × 10^6 cpm of α-^{32}P–labeled ATP. Appropriate drugs were added as required. The reaction was initiated by adding the membrane fraction to the incubation tubes. It was linear with respect to time (20 minutes) and protein concentration. The reaction was terminated by the addition of 0.25 ml of a solution

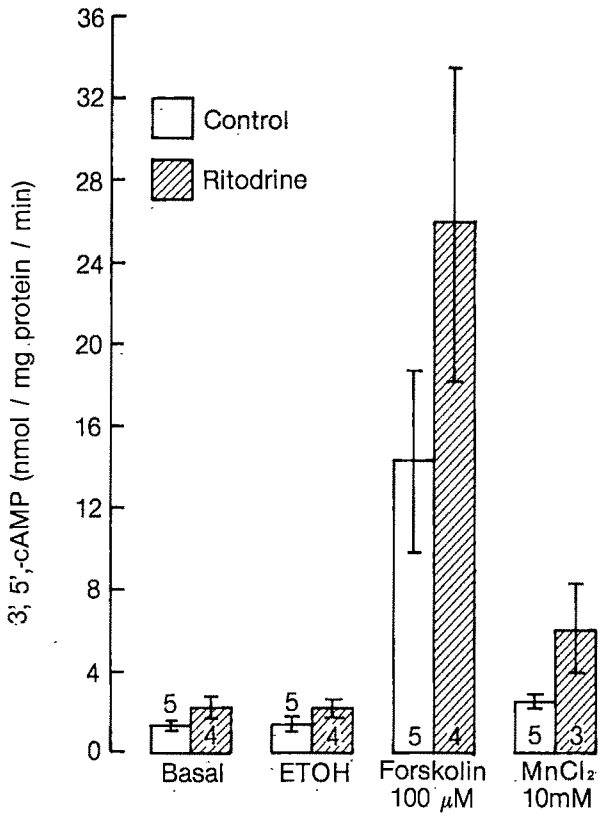

Fig. 4. Basal and stimulated forskolin- and manganese chloride *($MnCl_2$)*–dependent myocardial adenylate cyclase activity in pregnant adult rabbits. Ethyl alcohol *(ETOH)* (6%) was the diluent for forskolin; thus enzymatic activity was determined in its presence (not different from basal activity). *Numbers* in *bars* represent number of individual animals used for that determination.

containing 50 mmol/L Tris hydrochloric acid (pH = 7.5), 5 mmol/L ATP, 1 mmol/L 3′,5′-cAMP, and 5% sodium dodecyl sulfate. ^{3}H-labeled 3′,5′-cAMP (10,000 to 15,000 cpm per tube) was added to all tubes to serve as an internal standard and monitor the efficiency of recovery. The tubes were then placed in boiling water for 10 minutes and allowed to cool down to room temperature. ^{32}P-labeled 3′,5′-cAMP was isolated with sequential Dowex (AG 50W-X4, 200 to 400 mesh, Bio-Rad) and neutral alumina columns and counted in a scintillation counter (Packard). Recovery of 3′,5′-cAMP was determined by the percent recovery of ^{3}H-labeled cAMP external standard in each sample.

Results have been corrected for percent recovery (routinely >60%). Enzymatic activity was expressed as nanomoles of 3′,5′-cAMP produced per milligram of protein per minute (per heart). The K_{act} value of the enzyme for L-isoproterenol (concentration of L-isoproterenol required to half maximally stimulate enzymatic activity) was determined in some experiments by producing dose-response curves. K_{act} was calculated by logit-log transformation of the data from each individual dose-response curve.

Protein assay. Protein concentrations were determined according to the method of Bradford[8] with bovine serum albumin used as a standard.

Statistical analysis. Results presented are expressed as mean ± SEM. We used Student *t* tests to examine the null hypothesis that ritodrine treatment resulted in a decrease in basal and stimulated adenylate cyclase activity. A p value of <0.05 was considered significant.

Results

Adenylate cyclase activity in myocardial membranes was determined under several different experimental conditions. Basal enzyme activity in the presence or absence of guanosine triphosphate did not differ between the two groups (Fig. 1). However, the presence of guanosine triphosphate did increase basal adenylate cyclase activity to a modest degree. β-Adrenergic receptor–mediated adenylate cyclase activity was determined in the presence of maximal L-isoproterenol concentrations (Fig. 1) and by obtaining dose-response curves with variations in the amount of L-isoproterenol present (Fig. 2). L-Isoproterenol–dependent stimulation required the presence of guanosine triphosphate. The degree of stimulation by L-isoproterenol did not differ in the two treatment groups. Moreover, the K_{act} of the enzyme by L-isoproterenol was similar in the two groups of animals tested (Fig. 2). Finally stimulation by L-isoproterenol was specifically inhibited by DL-propranolol, a potent β-adrenergic receptor antagonist (Fig. 1). This series of experiments indicates that adenylate cyclase activity, which is mediated by β-adrenergic receptor stimulation, is not influenced appreciably by previous in vivo exposure to ritodrine.

We next indirectly examined the activity of the G_s-binding protein[2] as indicated by sodium fluoride stimulation (Fig. 3). Again, no significant differences were noted between the control and the ritodrine-treated animals. Sodium fluoride was not dependent on the presence of guanosine triphosphate.

Finally, we indirectly examined the catalytic component of the enzyme by measuring its stimulation in the presence of forskolin and manganese chloride (Fig. 4). We used these compounds since in previous experiments they have been shown to stimulate the catalytic component of the enzyme directly.[9-13] However, in some systems there is evidence to suggest that forskolin might accomplish this stimulation via a process dependent on G_s–binding protein. Forskolin was the most potent stimulator of enzymatic activity (Fig. 4). Addition of guanosine triphosphate to forskolin did not change the degree of adenylate cyclase stimulation (unpublished observations). Although manganese chloride stimulated enzymatic activity appreciably,

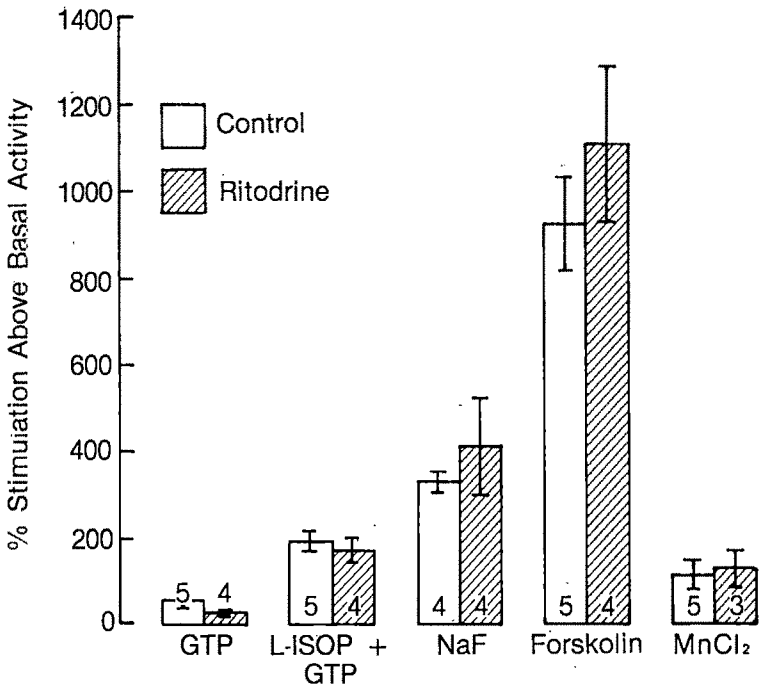

Fig. 5. Adenylate cyclase stimulation in myocardium of pregnant adult rabbits. Data from Figs. 1 to 4 have been normalized with regard to basal activity. No significant differences were noted. *Numbers* in *bars* represent number of individual animals used for that determination. *GTP* = Guanosine triphosphate; *L-ISOP* = L-isoproterenol; *NaF* = sodium fluoride; *$MnCl_2$* = manganese chloride.

it was significantly less potent than forskolin (Fig. 4).

Fig. 5 shows the percent activation over basal enzymatic activity by guanosine triphosphate, L-isoproterenol, sodium fluoride, forskolin, and manganese chloride. Forskolin was the most potent stimulant. However, the degree of stimulation by each of these agents did not differ between the control and ritodrine-treated animals.

In preliminary experiments we documented that the ritodrine hydrochloride we used to inject the animals did have in vitro activity in terms of both displacing ^{125}I-labeled iodohydroxybenzylpindolol from β-adrenergic receptors in myometrial membranes[14] and stimulating adenylate cyclase activity in myocardial membranes in the presence of guanosine triphosphate (unpublished observations). These experiments indicate that the ritodrine the animals received had not been inactivated.

Comment

Ritodrine is a potent selective β_2-adrenergic receptor agonist. However, it is similar to the other existing β-sympathomimetic drugs in that it acts to some degree on both β_1- and β_2-adrenergic receptors. The predominant subtype in ventricular myocardium is the β_1-adrenergic receptor.[4, 15] Thus it is not unusual to observe significant cardiovascular side effects as a result of ritodrine treatment. It has been shown[5] that ritodrine infusion results in significant maternal tachycardia and in a decrease in stroke volume and possibly in stroke work index. Finally, in some instances ritodrine has been associated with chest pain, congestive heart failure, and evidence of myocardial ischemia.

We hypothesized that in vivo exposure to ritodrine might result in down-regulation of myocardial β-adrenergic receptor function as manifested by adenylate cyclase activity in myocardial membranes from the adult pregnant rabbit.

To answer the question, we performed in vitro experiments in which we measured adenylate cyclase activity in ventricular heart membranes from pregnant rabbits. We found that daily intermittent treatment of rabbits with ritodrine did not result in any appreciable changes in myocardial adenylate cyclase activity. We did not see any changes in β-adrenergic receptor–mediated enzymatic activity nor did we observe an indirect effect on the function of G_s-binding protein or on the catalytic component of the complex. Thus under these experimental conditions ritodrine does not result in down-regulation of adenylate cyclase activity.

These results are somewhat in conflict with previously reported observations after isoproterenol treatment of animals where down-regulation of myocardial receptors had indeed been observed.[16] In that study, although L-isoproterenol was administered intermittently, the duration of treatment was for 10 days. How-

ever, desensitization has been reported even after a short-term infusion of L-isoproterenol. These results suggest that ritodrine may behave somewhat differently than isoproterenol and that it may affect only tissues that contain primarily β_2-adrenergic receptors. Finally, whether continuous, rather than intermittent, long-term infusion of ritodrine might result in desensitization of myocardial β-adrenergic receptors is not known.

Ritodrine has profound metabolic effects that might influence myocardial function regardless of β-adrenergic receptor and adenylate cyclase activity. Specifically, it has been associated with hypokalemia and hypocalcemia,[5] derangements that might affect myocardial cell repolarization and contractility. Thus it is possible that if ritodrine administration does not affect adenylate cyclase function in myocardial membranes, it might compromise it through secondary metabolic effects. Further work in this area to delineate the action of this drug with regard to myocardial performance is warranted.

Infusion of gonadotropin-releasing hormone agonist during pregnancy: Maternal and fetal responses in primates

V. M. Sopelak, Ph.D., and G. D. Hodgen, Ph.D.
Jackson, Mississippi, and Norfolk, Virginia

To determine whether a gonadotropin-releasing hormone agonist could cross the placenta to the fetus, each pregnant rhesus monkey (110 to 155 days' gestation, n = 10) and her in utero fetus had indwelling cannulas placed in the femoral veins. Gonadotropin-releasing hormone agonist (1000 μg intravenously) was injected into the mother (n = 8) or fetus (n = 2); serial blood samples were collected from mother and fetus for luteinizing hormone and follicle-stimulating hormone determination. None of the mothers responded to the gonadotropin-releasing hormone agonist bolus. In contrast, some of the fetal monkeys receiving gonadotropin-releasing hormone agonist via placental transfer and all fetal monkeys injected directly with the agonist responded as indicated by increased luteinizing hormone (2.8- to 12.3-fold) and follicle-stimulating hormone (1.5- to 8.9-fold) concentrations. In evaluating maternal and fetal effects, we found that continuous maternal infusion with either gonadotropin-releasing hormone agonist (n = 14) or saline solution (n = 11) throughout pregnancy did not alter maternal hormonal profiles. Histologically, gonads from their infants, removed within 3 days post partum, were normal. Although neonatal ovarian weights were unaffected by the in utero treatment, the testes weighed less ($p < 0.05$) in male infants born of mothers treated with gonadotropin-releasing hormone agonist compared to controls. Thus gonadotropin-releasing hormone agonist can cross from maternal to fetal circulation, and the fetus can respond (at least during the third trimester). (Am J Obstet Gynecol 1987;156:755-60.)

Key words: Gonadotropin-releasing hormone agonist, pregnancy, primates, gonadal development, gonadotropic hormones

Pulsatile administration of native gonadotropin-releasing hormone (GnRH) or other regimens for its agonistic analogs are being used increasingly in endocrine therapeutics.[1,2] Chronic treatment of experimental animals or humans with native GnRH or its synthetic agonistic analogs leads to decreased pituitary secretory responses and gonadal suppression in both male and female subjects.[1,3-5] Thus long-acting GnRH agonists are being evaluated for multiple medical indications, including prostatic cancer, endometriosis, contraception in women, uterine myeloma, breast cancer, and ovulation induction.

As with any medical agent, there is always a risk of pregnancy occurring during therapy in women of reproductive age. It is noteworthy that administration of GnRH or its agonistic analogs may initially evoke increases in luteinizing hormone and follicle-stimulating hormone secretion in adults, followed by down-regulation of the gonadotropes leading to a reduction of the total concentrations of follicle-stimulating hormone and luteinizing hormone.[4] If GnRH agonists pass easily from maternal circulation through the placenta to the fetus, there is concern about potential effects on fetal development, especially the gonadal and sex organ formative processes.

Studies using primates have shown that ablation of the fetal hypophysis leads to disorganized oogenesis and degeneration of an increased percentage of germ cells in the female neonate and a reduction in infant testes weights, percentage of Leydig cells, and spermatogonia per testis in infant primate males.[6,7] In anencephalic human fetuses surviving until term, hypoplasia of the ovaries and failure of normal progression of follicular maturation occurs.[8] Since these fetuses have less gonadotropin secretion resulting from a deficiency of pituitary function, it is thought that hypoplastic ovaries in neonates can result from lack of adequate gonadotropic stimulation during intrauterine life. Thus inadequate gonadotropic stimulation resulting from disease or surgery or brought about by drugs transferred across the placenta may disrupt normal fetal gonadal development.

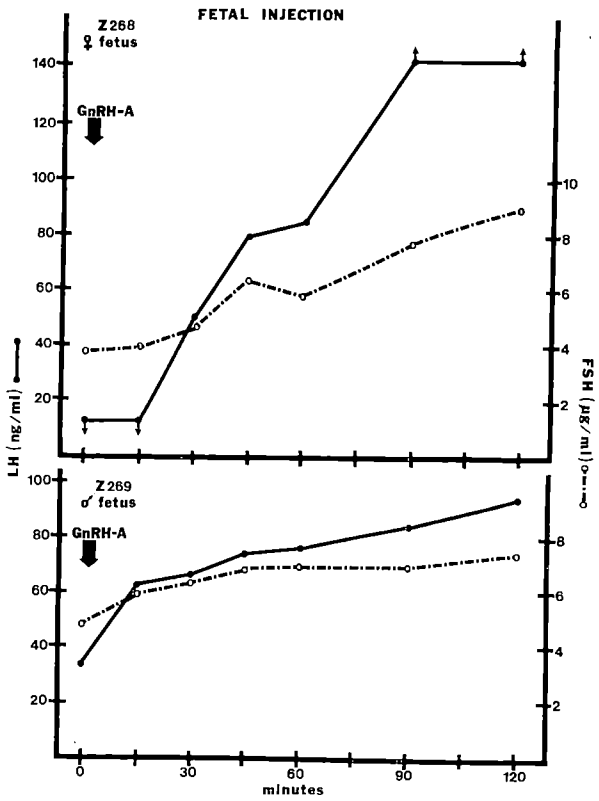

Fig. 1. Hormonal profiles of luteinizing and follicle-stimulating hormone secretion in a female and male fetus following an intravenous bolus injection of 1000 μg of a GnRH agonist (D-tryptophan[6], proline[9], GnRH). Note that the GnRH agonist elicits an increase in both gonadotropins within 30 minutes after injection.

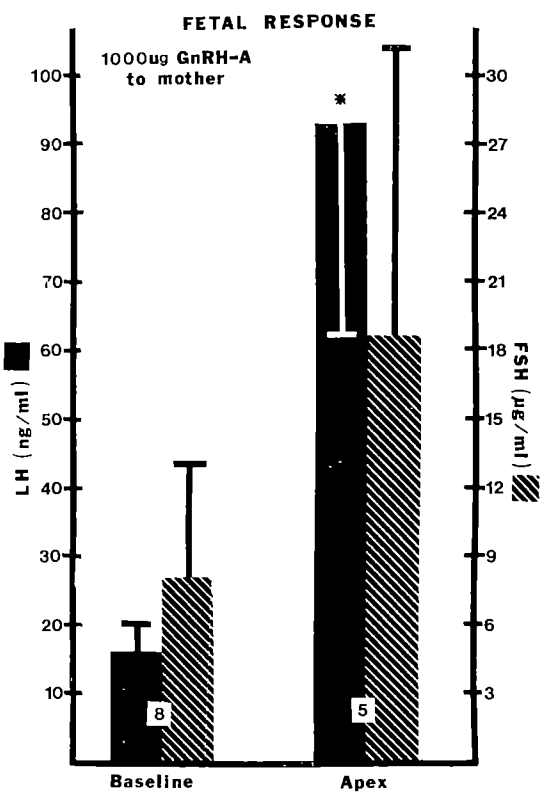

Fig. 2. Fetal gonadotropin response to maternal intravenous injection of 1000 μg of GnRH agonist. *Baseline* (mean ± SEM) levels of luteinizing and follicle-stimulating hormones are depicted for all eight fetal monkeys, while the highest concentrations of gonadotropins after GnRH agonist injection *(apex)* represent five fetal animals showing a response. These data indicate that GnRH agonist can traverse from maternal to fetal circulation via placental transfer.

In the present study we examined (1) whether a GnRH agonist, administered to the primate mother, would affect maternal hormonal levels; (2) whether this agonist would cross the placenta and stimulate fetal pituitary secretion of follicle-stimulating hormone and luteinizing hormone; (3) whether fetal gonadal development is affected morphologically; (4) whether postnatal pituitary response to castration is affected.

Material and methods

Animals. Female rhesus monkeys *(Macaca mulatta)* were caged individually in a controlled environment (temperature, 75° to 80° C; humidity, 60% minimum; lights on from 5 AM to 5 PM). The monkeys were given water ad libitum, fed a commercial monkey chow twice daily, and maintained with use of standard husbandry practices. From days 11 to 14 of the menstrual cycle, the female monkeys cohabitated with male ones of proven fertility. Conception was confirmed by a urinary nonhuman primate pregnancy test for chorionic gonadotropin[9] (provided by the Center for Population Research, National Institute of Child Health and Human Development, Bethesda, Maryland) performed on days 19 and 21 after mating and by palpation of the reproductive tract on day 35.

Study I. Placental transfer of GnRH agonist. To determine whether a potent GnRH agonist (D-tryptophan[6], proline[9] Net–luteinizing-releasing factor–ethylamide; provided by the Contraceptive Development Branch, National Institute of Child Health and Human Development) would cross the placenta and whether the fetal pituitary could respond to the GnRH agonist, each pregnant monkey (110 to 155 days' gestation, n = 10) and her in utero fetus was cannulated via the femoral vein after providing ketamine hydrochloride anesthesia (75 mg intramuscularly, Parke-Davis, Inc., Morris Plains, New Jersey). GnRH agonist (1000 μg in saline solution intravenously) was injected into the mother (n = 8) or fetus (n = 2). Blood (3.0 ml) was simultaneously collected from mother and fetus at 0, 15, 30, 45, 60, 90, and 120 minutes. Erythrocytes in saline solution were returned to each fetal monkey after the hourly samples were collected. Sera were harvested and stored frozen (−20° C) until radioimmunoassays

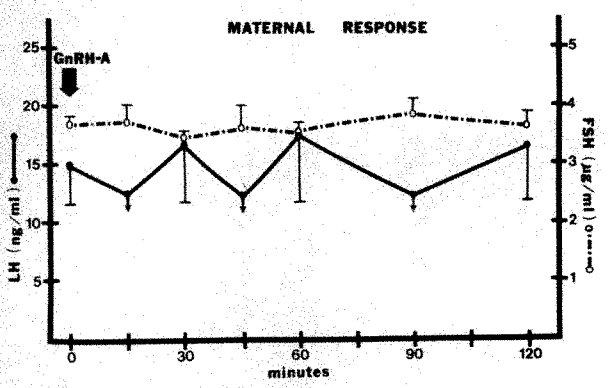

Fig. 3. Profiles of maternal luteinizing and follicle-stimulating hormone secretion (mean ± SEM) following a 1000 μg intravenous bolus of GnRH agonist. The steady state of gonadotropin concentrations are indicative of a pituitary that is unresponsive to GnRH agonist stimulation during pregnancy.

were performed for measurement of estradiol, progesterone, luteinizing hormone, and follicle-stimulating hormone as previously described.[10, 11] The R_{13} antiserum used for radioimmunoassay of monkey luteinizing hormone cross reacts with human luteinizing hormone, human chorionic gonadotropin, and comparable gonadotropins.

Study II. Continuous GnRH agonist infusion during pregnancy. GnRH agonist (6.6 μg/hr) was continuously administered to pregnant rhesus monkeys via a subcutaneous osmotic pump[12] (Model 2ML4; Alza Corp., Palo Alto, California) starting either during the first trimester (day 35 to term, n = 5) or third trimester (day 100 to term, n = 9). The osmotic pumps contained a 30-day supply of the agonist and were replaced at 28-day intervals. Control primates (n = 11) received saline solution (2.5 μl/hr). Maternal blood samples were collected every third day by venipuncture under ketamine hydrochloride anesthesia. Samples were frozen until assayed for estradiol, progesterone, luteinizing hormone, and follicle-stimulating hormone concentration. After spontaneous term delivery and within 3 days post partum, each infant monkey was weighed and anesthetized; its gonads were removed, weighed, fixed, serially sectioned, and stained with hematoxylin and eosin as previously described.[6, 7] A blood sample was obtained from each infant just before castration followed by weekly samples until 3 months of age. Sera were analyzed for concentrations of luteinizing hormone and follicle-stimulating hormone as previously described.[11] All samples from an individual monkey were analyzed in the same assay.

Data were compared with use of a one-way analysis of variance to determine whether ovarian weights, testis weights, and hormonal levels were different between infants born to saline solution–treated control monkeys compared to mothers treated with GnRH agonist. Since

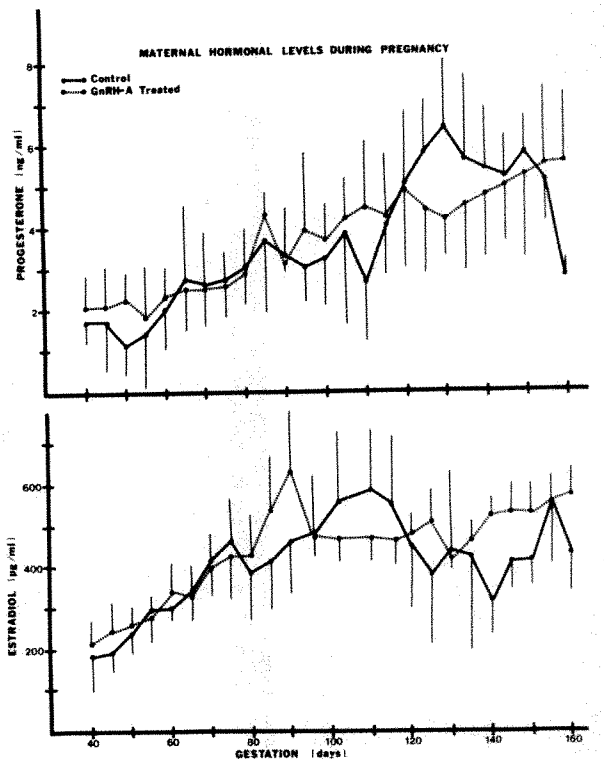

Fig. 4. Maternal hormonal profiles (mean ± SEM) of estradiol and progesterone secretion during pregnancy are unaltered from those of control primates, even when a GnRH agonist (6.6 μg/hr) is continuously administered during pregnancy via a subcutaneous osmotic pump.

such data from monkeys beginning treatment during the first or third trimester of pregnancy were statistically similar, the neonatal hormonal and gonadal data were combined and analyzed with respect to GnRH agonist treatment versus control.

Results

A bolus of GnRH agonist, when injected directly into the fetoplacental circulation in utero, elicited a prompt rise in fetal primate gonadotropin concentrations (Fig. 1). Similarly, when the agonist was injected into the maternal circulation, five of eight fetuses responded with a significant elevation of serum luteinizing hormone ($p < 0.01$) and a less dramatic rise in follicle-stimulating hormone concentration (Fig. 2). The remaining three fetal monkeys (>155 days of gestation) maintained gonadotropin values at the baseline. Thus placental transfer of the agonist did occur as judged by a rise in fetal gonadotropin levels in fetoplacental circulation. In contrast, none of the primate mothers showed any significant fluctuation in luteinizing hormone or follicle-stimulating hormone secretion following administration of this bolus of GnRH agonist (Fig. 3).

Maternal hormonal profiles of estradiol, progester-

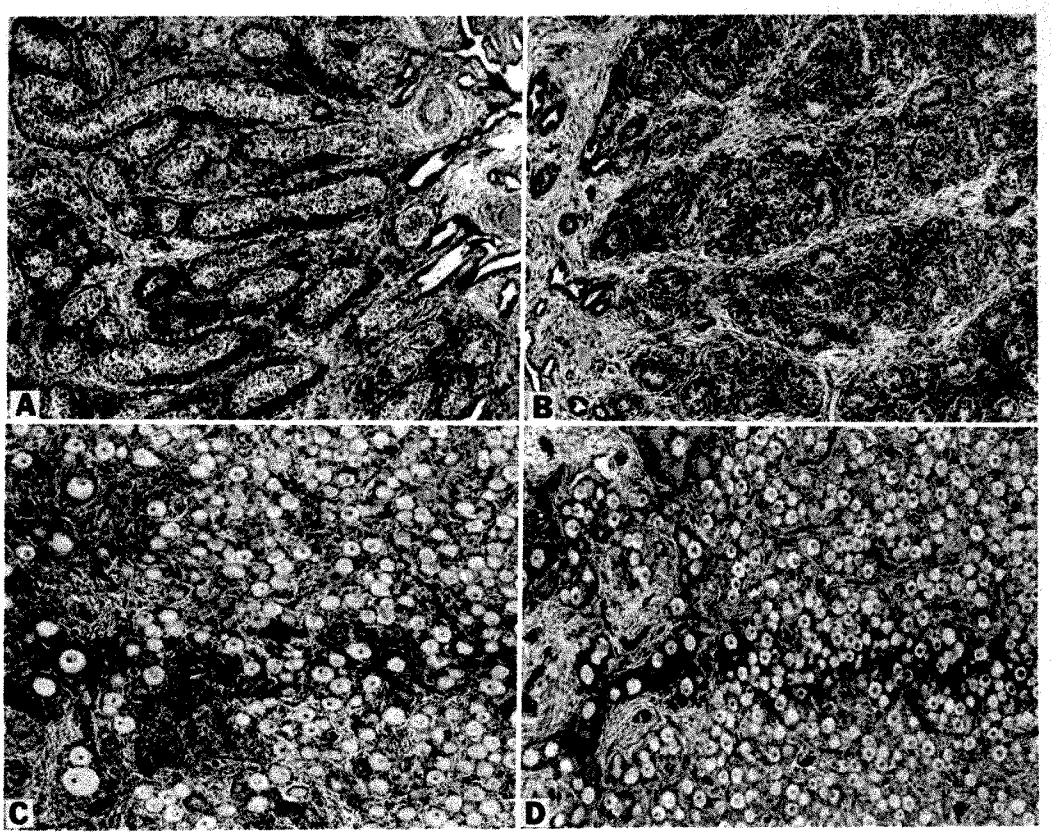

Fig. 5. Representative histologic sections of testis from a control infant *(A)* and a neonate whose mother was continuously treated during pregnancy with a GnRH agonist *(B)* are structurally similar. Sections of ovary from a control infant *(C)* and female neonate whose mother had received 6.6 μg/hr of GnRH agonist during pregnancy *(D)* are indistinguishable from each other.

one, luteinizing hormone, and follicle-stimulating hormone secretion were similar, irrespective of whether saline solution or GnRH agonist had been continuously administered throughout pregnancy (Fig. 4). The mothers treated with GnRH agonist maintained viable pregnancies (162.7 ± 1.9 days' gestation) and spontaneously delivered mature infants near normal term.[13]

At the time of delivery the genitalia of infants born from mothers treated continuously from either the first or third trimester with the GnRH agonist were normal in appearance. Histologically the gonads from treated and control neonates were indistinguishable (Fig. 5). However, testis weights were lighter ($p < 0.05$) in both groups of male infants treated with GnRH agonist, irrespective of whether treatment had started during the first or third trimester of pregnancy compared to controls (Table I). The differences in testis weight were not associated with differences in infant body weight (control vs. GnRH-treated male infants: 375 ± 30 gm vs. 415 ± 17 gm, respectively) or to significant differences in circulating gonadotropins (Table I), as measured within 3 days after birth. In contrast, neonatal ovarian weights were unaffected by the in utero infusion of the GnRH agonist. Luteinizing hormone and follicle-stimulating hormone concentrations were similar ($p > 0.05$) at the time of birth, irrespective of whether each female infants' mother received saline solution or GnRH agonist during pregnancy.

After castration, all treated and control infant monkeys responded to castration, manifesting steadily rising gonadotropin levels. By 5 weeks of age, gonadotropin values had risen from <15 ng/ml for luteinizing hormone and 2.3 ± 0.2 μg/ml for follicle-stimulating hormone in both male and female control infants to levels of 71.1 ± 24.8 ng/ml of luteinizing hormone and 24.1 ± 3.4 μg/ml of follicle-stimulating hormone. Similarly, castrate male and female infants born of mothers treated with GnRH agonist showed a progressive increase in luteinizing hormone (17.3 ± 2.1 to 115.7 ± 17.6 ng/ml) and follicle-stimulating hormone (4.3 ± 1.2 to >27 μg/ml) by 5 weeks of age ($p < 0.05$). Thus response of the pituitary to postnatal castration was not modified by in utero exposure to continuous GnRH agonist infusion.

Table I. Gonadal weights and hormonal values in newborn monkeys

	n	*Weight of gonad (mg)*	*Follicle-stimulating hormone (μg/ml)*	*Luteinizing hormone (ng/ml)*
Female				
Control	7	36.7 ± 3.8	2.1 ± 0.2	<15
GnRH agonist–treated	4	32.0 ± 2.8	6.1 ± 4.0	20.7 ± 7.5
Male				
Control	4	57.1 ± 5.4	2.8	<15
GnRH agonist–treated	6	42.9 ± 3.5*	3.3 ± 0.5	15.4 ± 0.5

*$p < 0.05$.

Comment

In this study we demonstrate that a GnRH agonist crosses from maternal to fetal circulation, often eliciting an increased pituitary-gonadotropin response from the in utero monkey as measured during the third trimester. That the luteinizing hormone response is of fetal rather than placental origin is plausible, since monkey chorionic gonadotropin is not detectable in serum, urine, or placental extracts beyond day 40 of pregnancy in the rhesus monkey,[14] there was a concomitant rise in fetal follicle-stimulating hormone after GnRH agonist injection, and there was no gonadotropin rise observed in maternal circulation. The findings of a fetal response to the GnRH agonist are consistent with our earlier preliminary data which showed that peptide hormones of 10 or 12 amino acids, such as native GnRH, could readily cross the placenta.[15] We are not surprised that three of eight in utero fetal primates did not respond to the maternal injection of GnRH agonist. Decreased placental blood flow caused by manipulation of the uterus and fetus during sample collection may have been a contributing factor. More important, however, may be the influence of gestational age. It is known that the responsiveness of fetal monkeys to in utero GnRH injections declines from day 100 to 160 of gestation.[16] Notice that all three unresponsive fetal monkeys in our study were of >155 days' gestation, whereas the five responders were less advanced.

Neither a bolus of GnRH agonist administered to the mother nor continuous GnRH agonist infusion throughout pregnancy altered maternal hormonal profiles. Other investigators have reported that both the human and monkey pituitary are unresponsive to acute GnRH stimulation during pregnancy.[15, 17] Elevated levels of steroid hormones (such as estradiol and progesterone) have been implicated in the refractoriness of the hypophysis to GnRH and its agonists during pregnancy. Although there have been reports that GnRH may induce increased secretion of chorionic gonadotropin from the placenta in the human, that mechanism is not well fitted to our observations in the rhesus monkey.

Since the maternal hormonal levels monitored during pregnancy were unaffected by continuous administration of the GnRH agonist, we postulate that any effect on the fetus may be due to changes in fetal physiology rather than to an altered maternal hormonal milieu. The cause of the reduction in testis weights of treated infants in this study is unknown. There were no concomitant reductions in infant body weight or a significant alteration in the architecture of the neonatal testis. Thus the effects of the GnRH agonist were not like those observed after surgical fetal hypophysectomy, in which the percentage of Leydig cells and spermatogonia per testis was reduced.[6, 7] Histologically the gonads of male infants exposed to GnRH agonist throughout gestation did not seem adversely affected.

The ovarian weights of female infants were unaffected by the GnRH agonist regimen. This finding should be contrasted with effects of fetal hypophysectomy during gestation which significantly reduced ovarian weight and germ cell number,[6] not unlike the results reported in male infants.[7] Although in utero exposure to the GnRH agonist was begun in some animals before completion of internal and external gonadal differentiation,[18] the genitalia of male and female infants were both normal. Pituitary response to castration in both male and female infants was in accordance with earlier results;[19] soon gonadotropin concentrations in castrate infant monkeys approached levels seen in castrate adult females.[20] Infants born of control mothers responded to castration in a similar fashion.

In conclusion, we have demonstrated that a long-acting GnRH agonist can easily cross from maternal circulation to the fetoplacental compartment in which the fetal pituitary responded (follicle-stimulating hormone/luteinizing hormone) to the agonist during the third trimester of pregnancy. Meanwhile, hormonal levels in the primate mother were unaffected. Despite a slight suppression of testicular weight at term, this GnRH agonist did not prevent virilization of males or induce ambiguous genitalia among female monkeys although administration in some monkeys was begun before internal and external gonadal differentiation was complete. Although we cannot comment on the potential teratogenic effects of GnRH agonist administration

before day 35 of pregnancy, we conclude that fetal in utero exposure after day 35 has little effect on overt gonadal development. However, longer-term follow-up studies are required to extend the level of safety suggested here, ultimately including demonstration of normal pubertal development and adult fertility.

We wish to thank the former members of the Pregnancy Research Branch, National Institutes of Health, for their helpful discussions and technical assistance. In addition, we are grateful to Dr. G. Bialy for providing the GnRH agonist used in this study, to the National Hormone and Pituitary Program for monkey follicle-stimulating hormone and luteinizing hormone kits, to Dr. W. Wiser, and to the faculty and staff of the Department of Obstetrics and Gynecology, University of Mississippi, for their research support.

CORRESPONDENCE

Müllerіosis instead of endometriosis

To the Editors:

Sanfilippo et al. (AM J OBSTET GYNECOL 1986;154: 39-43) present a case report of alleged endometriosis associated with müllerian anomaly. It is unclear from the diagram in their Fig. 1 how menstrual blood could escape from the fallopian tube into the abdominal cavity if the patient had a hematosalpinx on the right side. The foci of endometriosis were not sampled before or after their surgical treatment, so we do not know whether or not they really represented endometriosis. It is also unclear how they come to the conclusion that this was stage IV endometriosis, since higher stages of the American Fertility Society Classification require extensive adhesions, which were not shown in Fig. 1. It is unusual that they present two additional cases of müllerian anomaly, also without any objective proof that endometriosis was present. It will serve only to further confuse the literature on this important disease to let these loose clinical observations go unchallenged into the literature.

It is interesting to note that the relationship that the authors tried to develop between müllerian anomalies and supposed reflux menstruation and implantation of endometriosis has a parallel etiology that is possible. This and all previous reports describing this presumed association are equally strong arguments for "müllerіosis." Müllerіosis refers to a developmental defect of differentiation or migration of the müllerian duct system during embryology, with the resultant findings of displaced müllerian tissue in the adult manifested as endometriosis, endocervicosis, accessory fimbria, hydatids of the tube, cervical stenosis, as well as fusion defects of the uterus, cervix, or vagina. Endometriosis just happens to be the most common of these birth defects. Until this etiologic possibility is realized, we will continue to see articles jousting with the windmill of reflux menstruation.

To the Editors:

We are sorry that our diagram was unclear. There was significant intraperitoneal bloody effluent from the hematosalpinx. It is this effluent that we propose as being the source of the endometriosis.

The disease is described as having "deep ovarian involvement, partial obliteration of the cul-de-sac, and two-thirds enclosure of the ovary with dense and filmy adhesions." This scores 44 points (severe) on the American Fertility Society classification of endometriosis. Although biopsy evidence was not available in each case, it was available in case 2. There has been an additional case since publication of the original article in which biopsy evidence of endometriosis has also been established.

We appreciate Redwine's alternate explanation for our findings. His explanation, however, fails to address the two major points of our paper: (1) Spontaneous regression of the endometriosis occurred after elimination of the obstruction to menstrual flow in these patients. (2) Since spontaneous regression obviously does not occur in most patients with endometriosis, the entity we described after menstrual obstruction either is different from classic endometriosis or indicates that a permissive factor (such as immune incompetence) must work in concert with the reflux to present phagocytosis of the debris in most cases.

Nurse-midwifery care and improved outcomes

To the Editors:

In their article entitled "The perinatal and economic impact of prenatal care in a low socioeconomic population" (AM J OBSTET GYNECOL 1985;154:1), Moore et al. suggest three possible causes for the low prematurity rate (2% vs. 8%) in the Comprehensive Perinatal Program. We would like to postulate another possibility that was not considered in this article, that factor being the effect of nurse-midwifery care on improving outcomes.

Nurse-midwives have a long history of effecting improved perinatal outcomes.[1-9] The nurse-midwives of the Frontier Nursing Service provided care to poor, rural women in Kentucky. Most of the women who were delivered in their homes had limited resources. The Frontier Nursing Service had a maternal mortality of 1.2/1000 of 8596 births from 1925 to 1951. National maternal mortality rates were 6.73/1000 in 1931 and 3.76/1000 in 1940.[1]

Levy, Wilkinson, and Marin[3] in a 1971 study reported the impact of a nurse-midwifery program in Madera County, California.[3] During the program the prematurity rate was reduced from 11/1000 to 6.6/1000, which later rose to 9.8/1000 after discontinuance of the program. Neonatal mortality rose from 10.3/1000 during the program to 32.1/1000 after the program was discontinued. The authors related these significant changes to the type and quality of maternal/infant care provided by the nurse-midwives. During the program more prenatal care was given more frequently to a larger proportion of expectant women, and more women returned for their 6-week postpartum exami-

nations. There was a complete reversal of these trends after the program was discontinued.[3, 4]

In a 1985 study of nurse-midwifery management of adolescent pregnancy (with obstetrician consultation readily available) Piechnik and Corbett[5] reported a 50% decrease in low birth weight among adolescents under age 15, compared to the control group of adolescents cared for by state-supported maternal and child care clinics. This low birth weight rate of the nurse-midwifery group of all adolescents was 28% lower than the control group.

In 1981 Lehrman[6] reported that the average length of time of a prenatal visit with a nurse-midwife was 23.7 minutes, with a significant amount of the time spent on teaching and counseling during the visit. In the 1975 study by the National Ambulatory Medical Care Survey of office-based physicians, it was found that most prenatal visits were 10 minutes, with 32% of the visits no longer than 5 minutes and the visits including little counseling.[7] Additionally, Slome et al.[8] reported increased patient compliance in a randomized clinical trial of nurse-midwifery care compared to university house staff care.

The Institute of Medicine's 1985 report of the Committee to Study the Prevention of Low Birth Weight concluded that more reliance should be placed on nurse-midwives to provide prenatal care to groups at high risk for low birth weight. They also reported that important components of nurse-midwifery care that may prevent low birth weight include increased patient education and counseling, increased patient compliance with treatment plan and prenatal visits, and increased access to care. The benefit of these low cost interventions cannot be minimized in preventing low birth weight.[9]

Reply

To the Editors:

We appreciate the comments of McFarlin and Trupin regarding our article. Nurse-midwifery has certainly had a positive and admirable impact on prenatal care and obstetric outcome in this and other countries.

However, our study explored only the impact of prenatal care, or its absence, on pregnancy outcome. On careful reading it should be apparent that no conclusions whatsoever can be drawn with respect to what type of health professional provided the care.

Sonographic sign for Down syndrome

To the Editors:

A sonographic sign consisting of increased skin or soft tissue thickening at the back of the fetal neck during the second trimester was recently described as being highly specific for Down syndrome with no false positive findings (AM J OBSTET GYNECOL 1985;153:49-52). This finding could be very interesting, since it would allow a screening for all patients not undergoing chorionic biopsy or amniocentesis without arousing unuseful concern.

However, a note of caution should be employed interpreting this sign, since, at least in the third trimester, this finding does not appear to be specific for Down syndrome. In fact, we report two cases in which this sonographic sign did not correspond with Down syndrome.

The first case was a 37-week-old fetus affected by multiple malformations including a heart defect. This pregnancy ended in a stillbirth 2 weeks later, and a hydropic fetus was delivered.

The second case was a normal fetus at 38 weeks' gestation with a deflexed attitude, characterized by a thick nuchal skinfold, which was noted also in its legs when scanned tangentially. In each case the fetus showed this sonographic sign both in a sagittal and in a transverse scanning.

Furthermore, in transverse scannings abundant fetal hair may mimic this sign. Further studies are needed, at least in the third trimester, to define strict criteria for this promising sonographic sign.

Reply

To the Editors:

We appreciate very much the interest of Dr. Giacomello in our sonographic sign of increased skin or soft tissue thickening at the back of the fetal neck during the second trimester as a specific sign for Down's syndrome. Giacomello, however, reports two cases late in the third trimester in which this sonographic sign did not correspond with Down's syndrome. Our series only addresses fetuses in the second trimester between 15 and 20 weeks, and we have not looked at the accuracy of this diagnostic sign any later than 24 weeks.

We are in agreement that fetuses of the third trimester in a deflexed attitude can have a thickened nuchal fold at the back of the neck resulting from position, and this can certainly be a pitfall in looking at the fetal neck in the third trimester. Fetal hair can also be confusing, although more easily recognized as being separate from actual soft tissues.

Looking for the sonographic sign which we have described to be specific for Down's syndrome must be done cautiously, and to date, our findings only apply to fetuses of the second trimester, since our series only included second-trimester fetuses. We have not studied this sign or its specificity and sensitivity in third-trimester fetuses. Further studies are indeed needed for this purpose in order to define strict criteria for this sign outside of the second trimester.

Abdominal pelvic pain syndrome: Fact or fiction

To the Editors:

We read with interest the article by Slocumb on the abdominal pelvic pain syndrome (AM J OBSTET GYNECOL 1984;149:536) and the subsequent correspondence by Dhont et al. (1985;151:701-2).

Our recently published study[1] of pelvic venography in women with chronic pelvic pain without obvious organic cause shows beyond doubt that pelvic varicosities are present in the majority of these women. A venogram score of 5 or more clearly distinguishes women with pelvic pain syndrome from those who have an "organic" cause or have no pelvic pain (diagnostic sensitivity, 91%, and specificity, 89%). Abdominal pressure over the "ovarian point" commonly reproduces the pain complained of, especially on the right side. Our pelvic venography studies suggest that pressure over the ovarian point occludes the ovarian vein, and we have postulated that the resultant pain is due to the back pressure on the hilum of the ovary. We consider that pelvic pain has an organic as well as a psychological component and that the "fact or fiction" part of the title of Slocumb's article is no longer a valid question.

The treatment of this condition is not so clear. All pain must have a neurophysiological component, but we find it difficult to accept that abdominal trigger points exist in women with the pelvic pain syndrome which can be anesthetized to provide long-term cure of the pain. It should be noted that Slocumb's study is uncontrolled. There is no placebo and no controls without treatment, in the design, and hence conclusions about the efficacy of trigger-point anesthesia in this group of patients must be limited. The presence of pelvic varicosities and the predominance of the ovary as the site of the pain along with the history of long-standing emotional disturbance tend to support Taylor's concept of pelvic congestion as the somatic component of a psychosomatic disorder.

There can be no doubt of the very real need to establish an effective and easily applied therapy for this disabling condition. In view of the complex nature of pain experience, it is likely that an effective treatment will only be achieved when a better understanding of the etiology of pelvic varicosities and psychological factors in pelvic pain has been acquired.

Reply

To the Editors:

The letter by Beard, Reginald, and Pearce concerning their study on pelvic pain and varicosities[1] and opinions about trigger point abdominal wall pain[2] warrants an emphatic response. The authors have described the same observed painful tissues that are noted in the paper on trigger points, but they have not made an effort to reproduce that pain documenting the tissue of origin of the pain. The so-called "ovarian points"

are identical to the ileohypogastric tissues described by many[3] but have nothing to do with the underlying ovaries.[4]

If the authors were to perform the abdominal wall test by elevating the patient's legs to tense the rectus muscles, they would see that the pain exists in the wall above the rectus. If they were to explore slowly the ovarian point in the abdominal wall fat with a No. 22 needle, they would reproduce the same pain; if they were interested in helping the patient with her pain, they could infiltrate the pain point with 3 cc of ¼% bupivacaine to block the painful tissue.

What other observations have we seen which suggest that ovaries are not the main source of this pain? (1) The same pain is found in women with and without the ovaries, broad ligaments, and/or uterus.[4] (2) Gentle pressure over the abdomen with one finger is all that is needed to reproduce the pain without any deep compression to the vessels. (3) The same pain is present with or without varicies of the ovaries.[1]

I cannot comment on the author's observations about altered blood flow to the pelvis other than to say that pain alters sympathetic return with resultant vasodilatation in the same dermatome. Of note is the fact that their observations have no clinical value at this time in terms of altering the pain.

In conclusion, I cannot stress enough the importance of a few simple modifications of the physical examination in evaluation of pelvic pain. The finding of the abdominal wall component is crucial in avoidance of unnecessary procedures if not in treating the pain itself.

Use of midforceps and associated risk

To the Editors:

The latest item to fuel the debate over the use of midforceps and its associated risk is the article by Dierker et al. (AM J OBSTET GYNECOL 1986;154:764-8), which offers little comfort to protagonists. Although the authors deserve praise for their tempered recommendations against a return to difficult midforceps procedures, the paper may have a contrary effect on clinical practices. The fact that the major neurological sequelae were just as bad after midforceps use as after cesarean section will be interpreted by readers to indicate that midforceps delivery is safe despite the authors' disclaimer to the contrary. The report deals with infrequently done midforceps operations (0.8% over 6½ years) limited nearly exclusively to relatively "easy" procedures carried out under careful supervision after appropriate consideration of indications (and contraindications, no doubt) in highly selected circumstances, conditions not likely to be capable of duplication in very many communities. It is dubious in fact that the model—or its results—could be translated into practical reality at large.

Several points deserve special comment. First, nearly 38% of the index cases were lost to follow-up. Given this large proportion, some attempt should be made to ascertain the degree of bias this may have introduced. Pollsters now recognize that nonrespondents can no longer be ignored because the reason they do not cooperate may be related to the very issue under study. Many of the cases lost to follow-up here may therefore be those who did not turn out well. Clearly, if the lost group did contain a substantially greater frequency of the more seriously affected children, the validity of the findings would be open to question. Although the pairing design used for the study helps overcome some of this effect, it nonetheless deserves to be addressed. Second, the matching process did not include the delivery year. Because case finding extended over >6 years, it might have been prudent to consider that subtle (or perhaps overt) changes in obstetric and pediatric care practices during this interval needed to be taken into account. This turned out to be an unexpectedly important confounding factor, for example, in one of our studies of the impact of fetal heart rate monitoring.[1] Third, the time factor may also have had a further influence on the outcome findings, especially if the mean follow-up duration was shorter for the midforceps offspring than for those delivered by cesarean section. The earlier the date of the delivery, the longer the opportunity for follow-up and the greater the probability of loss to follow-up. Furthermore, the longer the follow-up, the greater the likelihood of uncovering adverse effects. Fourth, major labor disorders were collapsed under the term "dystocia" (by which we assume the authors intended to convey the concept of obstructed labor). Since only about half such cases are related to documentable cephalopelvic disproportion, it is a matter of chance that midforceps and cesarean section cases will be properly matched for this factor. In addition, it was likely for the more obviously disproportionate cases to be delivered by section, thereby further diminishing their comparability. Dystocia in the midforceps group was also far more likely to be associated with arrest of descent, whereas cesarean sections, except those undertaken in the second stage, were done more often in conjunction with protracted or arrested dilatation. Fifth, the same criticism probably applies to

matching for fetal distress. The criteria used to define it are not given in the paper. Moreover, the criteria have varied over the past decade, they are still not uniformly defined or accepted, and the diagnosis is associated with a high frequency of false positives. Reliable matching can thus be challenged. Sixth, no neurological, psychological, or intelligence testing or formal examinations were actually done for purposes of acquiring uniform and reliable information for this report, which is based instead on chart reviews and interviews. Gross deficits can probably be detected in this way, but subtle disorders are easy to miss. The more subtle deficits in speech, language, hearing, abstract and cognitive thinking, behavior, and so-called neurological soft signs are more common, more difficult to detect objectively, and take a longer follow-up time to assess adequately or to disclose definitively.

Finally, the results can just as logically be interpreted rather differently: Serious obstructive or hypoxic labor problems were shown to impact adversely on the fetus regardless of the mode of delivery, perhaps related to delays in detection, evaluation, and expeditious interventive management, and whatever additional deleterious effect the delivery may have had was not large enough to be detected by this investigative approach. This conclusion is analogous to the Scottish legal verdict of "not proved" and carries a very different meaning from that given by Dierker et al. who went too far (without objective justification, we believe) when they wrote "selected midforceps procedures may be performed with no greater risk of abnormal outcome than that associated with cesarean section," the equivalent to a "not guilty" verdict. Not proving harm is patently not the same as proving no harm. We would therefore admonish obstetricians to avoid the temptation of misinterpreting the results of this study as giving them license to turn back the clock.

Reply

To the Editors:

We are pleased with Friedman and Acker's interest in our paper and appreciate the opportunity to respond to their comments. As noted by Friedman, nearly 38% of the index cases were lost to follow-up. Attempts were made to locate the family when the child's chart could not be located. The inability to locate the family therefore would not imply poor outcome for those who could not be located. Data were obtained for all subjects who were located. We do not anticipate significant bias, since the family could not be located. The situation would clearly be different if the subjects were adults without dependent family ties. The paired design was meant to minimize this effect.

The match for the midforceps group included birth weight within 200 gm, gestational age within 2 weeks, sex, race, dystocia (arrest or protraction), as well as fetal heart monitoring suggesting fetal distress. The match was made for the best subsequent match delivered by cesarean section. The follow-up for the midforceps group was therefore longer, allowing more time to uncover abnormalities. In addition, more current technology would have been available for the cesarean section group delivered later. These factors would tend to bias in favor of the cesarean group.

Friedman criticized the combination of labor disorders under the term "dystocia." Dystocia in our paper referred to arrest and protraction disorders of active and second-stage labors. The disorders were grouped, since his study (1) showed no difference between arrest or protraction disorders and intelligence quota scores—they were diminished equally. It may well be that the cesarean group contained a greater degree of cephalopelvic disproportion than the midforceps groups, but attempting to match for the degree of disproportion is not currently feasible.

As noted by Friedman, the fetal distress match was not identical. The criterion used for matching was a fetal heart rate pattern that pushed the clinician to act because of concern for fetal well-being. These patterns included late decelerations, severe variable decelerations, and bradycardias. Individual patterns and degree of severity, confirmed by scalp pH would have been ideal, but were not possible. The patterns were of sufficient concern to precipitate obstetrical intervention by either midforceps or cesarean section.

The criticism that individual formal testing was not prospectively applied was fully appreciated and mentioned in our paper. Pediatric clinic and office visits included developmental assessment of the child as an integral part of the visit. The history is designed to detect developmental delays and speech difficulties as well as health status. When abnormalities were suspected from this evaluation, children were referred for specialized analysis. The abnormalities noted in our paper were confirmed abnormalities.

Finally, in the last three paragraphs of the discussion we stated that one could not conclude the midforceps were safe. Our study was based on relatively "easy" midforceps usually from the +2 station or lower. Midforceps were not used strictly for training purposes, and continued fetal observation was encouraged. Cesarean section under those conditions was not associated with improved outcome. This is a far cry from recommending a return to difficult midforceps procedures, which we specifically note in the final paragraph of our paper.

Finally, we would note, as have Friedman et al.[1] and other authors in similar reports, that many questions regarding midforceps cannot be answered without randomized prospective studies, which are not likely to be conducted today. However, our study compared midforceps management with matched cesarean section patients, a comparison that Friedman could not do with their data. Our report suggests that altering birth route did not alter outcome. Perhaps the only way to avoid poor outcome associated with dystocia is to avoid dystocia.

Kell sensitization in pregnancy

To the Editors:

I am concerned by the implications and recommendations from the article by Caine and Mueller-Heubach on Kell sensitization in pregnancy (Am J Obstet Gynecol 1986;154:85-90).

The recommendation is that when the maternal anti-Kell titer is <1:32 (Coombs technique) good care requires only monthly anti-Kell titers starting at 23 weeks. Nothing could be further from the facts. In our own experience and the experience of several others, fetal hydrops and death have been seen with titers <1:32.

The implication that titer levels from one laboratory can be compared to titer levels from another and have the same clinical implications reflects a lack of understanding of the concept of the "critical titer" level. Clarification is needed to prevent mismanagement.

Reply

To the Editors:

We appreciate the comments of Dr. Frigoletto regarding our paper on Kell sensitization in pregnancy. Our paper describes our experience with Kell sensitized pregnancies in which maternal anti-Kell titers <1:32 were not associated with significant adverse neonatal outcome. This is based on the large-scale experience of our laboratory with use of a standardized laboratory procedure for antibody titer determination. The great variation from one laboratory to another in titer determinations is well known. Therefore we never rely on antibody titers from other institutions when patients are referred to us but repeat these titers in our own laboratory. It is of interest that Dr. Frigoletto has seen fetal hydrops with a titer of 1:32 secondary to Kell sensitization. This value would have prompted us to do the full investigation outlined in our paper. Recently a case of fetal hydrops with an anti-Kell titer of only 1:4 has been reported.[1] In view of our very large series of Kell sensitized pregnancies with good outcome when the anti-Kell titer was <1:32 it appears unlikely that we were merely fortunate. It is more likely that differences are due to the variation in antibody titer determinations between laboratories which are well known and have been emphasized again by Dr. Frigoletto in his letter.

Selection of study patients with premature rupture of membranes

To the Editors:

We read with considerable interest the report of Morales et al. (Am J Obstet Gynecol 1986;154:591-5) regarding the use of dexamethasone administration in the management of patients with preterm rupture of the membranes. This diagnosis constitutes a large segment of our maternal-fetal transport population, and insight into management strategies that will improve the outcome for mothers and infants would be extremely helpful. Unfortunately, the authors missed an opportunity to answer definitively the question of whether glucocorticoid administration is useful in the prevention of the respiratory distress syndrome in patients who have premature rupture of the membranes.

The authors state that they excluded patients in whom phosphatidylglycerol was present in the vaginal pool. Did all the *included* patients have vaginal pools assessed for the presence of phosphatidylglycerol? How was it measured? Phosphatidylglycerol assessed by Amniostat was negative in >70% of patients at Denver General Hospital whose lecithin/sphingomyelin ratios

were >2. Indeed, even in the absence of phosphatidylglycerol by any determination, the authors would have to agree that the risk of respiratory distress syndrome is considerably different with an lecithin/sphingomyelin ratio of 0.8 to 1 as opposed to a ratio of 1.8 to 1. Apparently, amniocenteses were not done in an effort to stratify treated and untreated patients by the degree of the immaturity of their lecithin/sphingomyelin ratios. This is an absolutely critical determination if one hopes to answer the question of the merits of glucocorticoids in patients with premature rupture of the membranes, since these patients represent a highly selected group of preterm gestations whose amniotic phospholipid status is significantly different from control values.

Their own data from Table III reflects this important point.

Among the 27 steroid-treated patients with a latency period of less than 24 hours, only 26% (seven patients) experienced respiratory distress syndrome as compared to 54% (35 patients) with a similar latent period and no steroid treatment. If enzyme induction of surfactant production is the mechanism by which steroids influence the occurrence of respiratory distress syndrome, certainly <24 hours is insufficient time to affect surfactant production; therefore this significant diminution from control must be explained by another reason. As the latent period increased past the "critical" 24- and 48-hour periods, no further reduction in respiratory distress syndrome is seen. This does not seem to us a biologically reasonable result. Rather, it is more easily explained by the inclusion in the steroid-treated group of some patients whose risk of respiratory distress syndrome is low; for example, a lecithin/sphingomyelin ratio of 2.2 to 1 with no phosphatidylglycerol. Though one might argue that with sufficiently large groups, the prevalence rate of very low, moderately low, and nearly mature lecithin/sphingomyelin ratios would be evenly distributed, this remains to be shown. The only study that satisfactorily addresses this problem to date is that of Garite et al.[1] in which all patients included had lecithin/sphingomyelin ratios of <2. As Morales et al. point out, that study showed no significant difference in the incidences or severity of respiratory distress syndrome in steroid or control groups. Even in that study, it would have been interesting to have patients stratified even further into very low lecithin/sphingomyelin ratios versus nearly mature lecithin/sphingomyelin ratios to note any differences associated with steroid use. It may be that the subgroups would be too small to be of any statistical usefulness, though the very low lecithin/sphingomyelin ratio subgroup are the patients for whom steroid therapy may potentially have some merit.

Even in the absence of infectious morbidity in the current study, it should be noted that tocolytic therapy was required in 44 patients, including two patients who had acute pulmonary edema. The mere absence of phosphatidylglycerol from a vaginal pool is unsatisfactory information in our view to prolong a pregnancy with tocolysis in the face of ruptured membranes in order to administer steroids. Additional information regarding the true risk of respiratory distress syndrome in these infants as well as ruling out subclinical infection by amniocentesis is necessary to plan intelligently management strategies for these high-risk pregnancies.

Reply

To the Editors:

We appreciate the interest of Porreco and Burke in our work and thank them for their comments.

Phosphatidylglycerol was determined from samples obtained from vaginal pool by thin-layer chromatography, although since 1985 it is being assessed by Amniostat. This was generally determined in the more mature preterm gestations of ≥32 weeks. While we do agree that the risk of respiratory distress syndrome is decreased by increased lecithin-sphingomyelin ratio, the preterm infant of <32 weeks is at risk of other serious complications such as intraventricular hemorrhage and retinopathy of prematurity; although their incidences are increased by the severity of their respiratory distress, mild respiratory distress syndrome could still result in significant rates. Nonetheless, we are currently evaluating as a part of a study investigating other treatment modalities, data on the effects of dexamethasone on preterm pregnancies with different lecithin-sphingomyelin ratios. In regard to the results of Table III, latency period in this study was defined (as noted in the text) as the time from rupture of membranes to the onset of labor, *not* to delivery. Although 27 patients in the steroid treatment group had a latency period of <24 hours, 22 (81%) completed their course of therapy by the complementary use of intravenous tocolytic agents.

ORTHO-NOVUM 1/77

TRADEMARK

Tablets

(norethindrone/ethinyl estradiol)

Enhanced patient compliance

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may cause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who are pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study conducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than that of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study conducted in the United States found that past use of oral contraceptives was associated with increased risk of subarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk may be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists following discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

UNIQUE

Full-cycle endometrial support, with no late-cycle progestin increase.

The unique TRI-NORINYL phasing achieves BTB control equivalent to a 1/35 formulation, but with 29% less progestin per cycle. This is, in fact, the greatest progestin reduction of any norethindrone-based multiphasic. TRI-NORINYL lowers progestin where requirements for endometrial support are reduced–with no greater reported BTB than a 1/35 formulation.*

SUPPLIED IN THE EXCLUSIVE SYNTEX WALLETTE™ PILL DISPENSER

Preferred by patients 3 to 1 over other available packages for convenience, discreetness and compliance.**

THE NATURE OF TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

*1/35 formulations contain 1.0 mg norethindrone with 0.035 mg ethinyl estradiol. Data available from Syntex Laboratories, Inc.

**Based on a nationwide, independently conducted survey of prospective oral contraceptive patients. Data available from Syntex Laboratories, Inc.

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of full prescribing information on next page.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34 – 5/100,000; ages 35-44 – 33/100,000; ages 45-49 – 140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34 – 1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over – 1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only; smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS – RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40+
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A – Use associated with very high risk.
B – Use associated with high risk.
C – Use associated with moderate risk.
D – Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer in OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones – estrogenic and progestational agents – during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests *Chlamydia trachomatis* infection, the leading cause of nongonococcal P.I.D., is enhanced by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure. **Information for the Patient** (See Patient Package Insert).

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

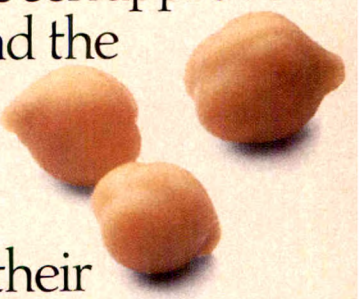
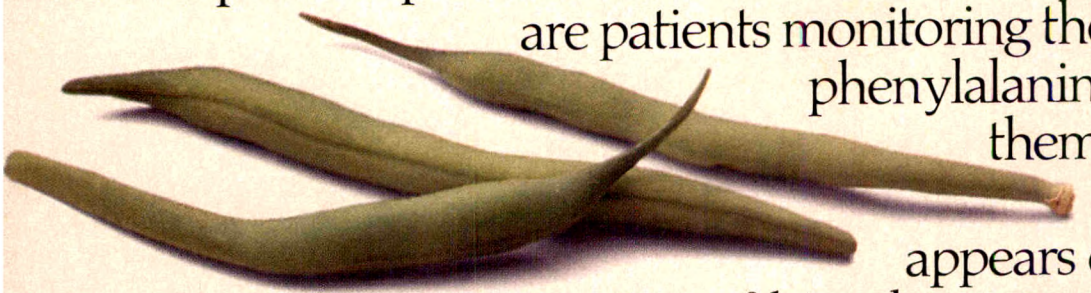
Your body doesn't know NutraSweet® from beans.



Or peas. Or grapes. Or milk.
Or chicken for that matter.
Because NutraSweet®
brand sweetener is a
dipeptide made of two amino acids.
(Aspartic acid and phenylalanine as the methyl ester.)



So even though NutraSweet doesn't come from fresh food, it might as well have. Because once past the taste buds, it's digested just like any other simple protein.

No wonder aspartame has been approved by the FDA, the WHO, and the regulatory agencies of more than 50 countries.

The only people who need to limit their consumption of products with NutraSweet, are patients monitoring their phenylalanine intake. For them, an informational label appears on every product containing NutraSweet® brand sweetener.

If you'd like more information, just call 1-800-321-7254.

It's nice to know that with NutraSweet, people who need to cut back on sugar are finding it easier to enjoy something sweet now and then.

YES OR NO. STAT.

This AccuPoint™ Test Disc is virtually a 2-inch lab. As part of the new AccuPoint hCG Pregnancy Test, it offers the ultimate in sensitivity, versatility and convenience by detecting hCG levels as low as 20 mIU/mL—using *either* urine or serum samples.

The same AccuPoint Test Disc is the focus of a growing *system* of non-instrumented, in-office tests offered by Syntex, one of the most trusted names in health care.

All AccuPoint diagnostic tests offer similar protocols, so it's simple to administer a *series* of tests—such as Rubella, Toxo and the hCG Pregnancy Test—for optimum patient care.

Fill out and mail the coupon below for our special offer. And start enhancing your practice now, with the AccuPoint 2-inch lab.

HOW MANY NEW DRUG ADDICTS HAVE YOU DELIVERED?

Even one more addict adds to the staggering number of drug abusers in our society. You, as a physician, are in a unique position to help reduce this number. Just ask your patient a simple question during her initial workup: *Are you using drugs?* Asking about drug use is no more an invasion of privacy than asking about exposure to German measles. It's just as important to her baby's health. And knowing about it may prevent serious problems for you, mother, and baby. Help free this generation—and the next—from drugs.
Remember...

You'll never know unless you ask.

Medical Staff Fellowships In Genetics, Endocrinology, And Developmental Biology At NIH

The National Institute of Child Health and Human Development of the National Institutes of Health is offering a limited number of three-year Medical Staff Fellowship positions to candidates of the highest caliber. Fellowships begin July 1, 1989 and 1990. Positions are available for physicians who have completed at least two years of training in Internal Medicine, Pediatrics, or Obstetrics and Gynecology. Other medical specialty credentials will be considered on a case by case basis. Candidates must be United States citizens or permanent residents; graduates of foreign medical schools must be certified by the ECFMG. (Non-citizens wishing only laboratory experience may apply for the Fogarty Visiting Fellowship and do not need ECFMG certification.)

The training program consists either of one clinical year and two years of laboratory-based research (satisfying the requirements for the Subspecialty Boards in Human Genetics, Adult or Pediatric Endocrinology, or Gynecologic Endocrinology), or three years of laboratory research exclusively. The endocrinology fellowships are integrated with the NIH Interinstitute Endocrinology Fellowship Program, and the human genetics fellowships are integrated with the NIH Interinstitute Medical Genetics Program. The gynecologic-endocrinology fellowship is integrated with programs at the Walter Reed Hospital and the National Naval Medical Center.

For those selecting clinically oriented fellowships, research experience will be obtained in the Laboratory or Branch of the Fellow's choice from among the Institute's three clinical research Branches and nine basic science Laboratories. For those candidates selecting laboratory research exclusively, these same choices are available.

The major emphasis of the NICHD Intramural Research Program is on basic and clinically applied research in the broad area of developmental biology. Areas presently being examined include developmental endocrinology, reproductive biology, cellular differentiation, human genetics and inborn metabolic errors, molecular endocrinology, developmental and molecular immunity, developmental neurobiology, molecular genetics (bacteria, virus, yeast, drosophila, and animal cell), pharmacogenetics, growth factors, neurochemistry and neuroimmunology, theoretical and physical biology, cell biology (especially receptors and organelles), and comparative ethology.

For physicians interested in pursuing a career in academic medicine and research, these Fellowships offer an opportunity to train with scientists and physicians of international stature. Excellent facilities are available on the 306-acre NIH campus in Bethesda, Maryland, including a 480-bed research and teaching hospital, more than 1,000 laboratories, and the National Library of Medicine. Medical Staff Fellows receive an initial salary of $30,000 with increments of $2,000 per year. Moving and traveling allowances, and Federal health care benefits are available.

Interested candidates should send their curriculum vitae to (or request further information from):

Arthur S. Levine, M.D., Scientific Director,
National Institute of Child Health and Human Development,
National Institutes of Health, 9000 Rockville Pike,
Building 31, Room 2A50, Bethesda, Maryland 29892, (301) 496-2133

NIH is an Equal Opportunity Employer.

Deadline for applications is November 15, 1987.

Faculty Position in Maternal-Fetal Medicine

The Department of Obstetrics and Gynecology at Wright State University School of Medicine invites applications for a full-time faculty position in Maternal-Fetal Medicine combined with the position of Medical Director of a regional perinatal care center.

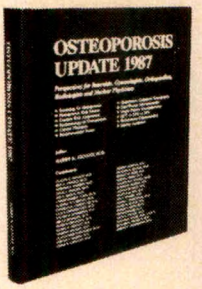
Primary duties will include the teaching of medical students and residents, the pursuit of scholarly activities, and the medical administration of the perinatal center which includes the obstetrical unit and the labor and delivery suite.

Applicant qualifications include the M.D. degree, board certification in obstetrics and gynecology, licensibility to practice Medicine in Ohio, completion of a fellowship in maternal-fetal medicine, board eligibility or certification in maternal-fetal medicine, and extensive training and experience in perinatal medicine and administration of health services. Academic rank and salary will be commensurate with qualifications and professional experience. Please send curriculum vitae and the names of three references to: John J. Halki, M.D., Ph.D., Chair and Program and Director, Department of Obstetrics and Gynecology, Wright State University School of Medicine, 1 Wyoming Street, Dayton, OH 45409.

The Wright State University School of Medicine is an Affirmative Action and Equal Opportunity Employer.

All applications received by September 30, 1987 will be considered; if the position is not filled therefrom; applications will be considered as received until the position is filled.

OB-GYN



OB-GYN TEACHING FACULTY AT TRUMAN Medical Center/East, one of two teaching hospitals for the University of Missouri-Kansas City School of Medicine. Joint faculty appointments in Departments of Family Medicine and OB-GYN. Primary responsibilities teaching OB and office GYN to Family Practice residents, performing GYN surgery, some lesser involvement with medical students, and consultation in high-risk pregnancy problems as they present. Competitive salary, excellent fringes, opportunities for additional practice, if desired. Contact Family Medicine Department, University of Missouri-Kansas City School of Medicine, Truman Medical Center-East, 7900 Lee's Summit Road, Kansas City, MO 64139. (816) 373-6228. Attention: Thomas A. Nicholas, M.D., Chairman.

MOSBY Medical Journals

Medical specialty publications bringing important medical literature to over 205,000 worldwide subscribers throughout the year. MOSBY journals provide information progressive physicians need to maintain a continuing education program in their specialty areas. **SAMPLE COPIES of journals are available.**

* **THE JOURNAL *of* ALLERGY *and* CLINICAL IMMUNOLOGY**
Monthly. Institutions: $92.00; Individuals: $45.00; Students, residents: $32.00. Official publication of the American Academy of Allergy and Immunology.

CLINICAL NUTRITION
Bimonthly. Institutions: $39.00; Individuals: $39.00; Students, residents: $21.00.

* **CLINICAL PHARMACOLOGY *and* THERAPEUTICS**
Monthly. Institutions: $113.00; Individuals: $65.00; Students, residents: $45.00. Official publication of the American Society for Pharmacology and Experimental Therapeutics and the American Society of Clinical Pharmacology and Therapeutics.

* **JOURNAL *of* THE AMERICAN ACADEMY *of* DERMATOLOGY**
Monthly. Institutions: $104.00; Individuals: $57.00; Students, residents: $36.00. Official publication of the American Academy of Dermatology.

* **THE JOURNAL *of* HAND SURGERY (American Volume)**
Bimonthly. Institutions: $85.00; Individuals: $38.50; Students, residents: $25.00. Official publication of the American Society for Surgery of the Hand.

* **AMERICAN HEART JOURNAL**
Monthly. Institutions: $98.00; Individuals: $51.00; Students, residents: $33.00.

* **HEART & LUNG: THE JOURNAL *of* CRITICAL CARE**
Bimonthly. Institutions: $68.00; Individuals: $21.00; Students, residents: $16.00.

* **AMERICAN JOURNAL *of* INFECTION CONTROL**
Bimonthly. Institutions: $66.00; Individuals: $19.75; Students, residents: $15.00. Official publication of the Association for Practitioners in Infection Control.

* **THE JOURNAL *of* LABORATORY *and* CLINICAL MEDICINE**
Monthly. Institutions: $109.00; Individuals: $62.00; Students, residents: $35.00. Official publication of the Central Society for Clinical Research.

* **AMERICAN JOURNAL *of* OBSTETRICS *and* GYNECOLOGY**
Monthly. Institutions: $102.00; Individuals: $59.50; Students, residents: $40.00. Official publication of the American Board of Obstetrics and Gynecology, The American Gynecological and Obstetrical Society, plus 32 regional societies.

* **OTOLARYNGOLOGY—HEAD *and* NECK SURGERY**
Monthly. Institutions: $115.00; Individuals: $70.00; Students, residents (non-Academy members): $45.00; Residents (Academy members): $20.00. Official publication of the American Academy of Otolaryngology–Head and Neck Surgery, the American Academy of Otolaryngic Allergy, and the American Neurotology Society.

* **THE JOURNAL *of* PEDIATRICS**
Monthly. Institutions: $95.00; Individuals: $47.50; Students, residents: $30.00.

* **SURGERY**
Monthly. Institutions: $97.00; Individuals: $49.50; Students, residents: $32.00. Official publication of the Society of University Surgeons, Central Surgical Association, and the American Association of Endocrine Surgeons.

* **THE JOURNAL *of* THORACIC *and* CARDIOVASCULAR SURGERY**
Monthly. Institutions: $118.00; Individuals: $70.00; Students, residents: $45.00. Official publication of the American Association for Thoracic Surgery and the Western Thoracic Surgical Association.

* **JOURNAL *of* VASCULAR SURGERY**
Monthly. Institutions: $98.00; Individuals: $57.00; Students, residents: $35.00. Official publication of the Society for Vascular Surgery and the International Society for Cardiovascular Surgery (North American Chapter).

THE JOURNAL *of* HEART TRANSPLANTATION *new*
Bimonthly. Institutions: $60.00; Individuals: $40.00; Students, residents: $25.00. Official publication of the International Society for Heart Transplantation.

* Included in Index Medicus

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Zuspan is responsible for articles from the Society for Gynecologic Investigation. Manuscripts should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033. Dr. Quilligan is responsible for articles from The Society of Perinatal Obstetricians. Manuscripts should be submitted to Dr. John A. Read, 9102 Lake Steilacoom Point Road, S.W., Tacoma, WA 98498.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Edi-

tor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manuscript and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper with good color balance. For black and white illustrations, submit three sets of 3 by 4 inch (minimum) to 5 by 7 inch (maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black and white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.

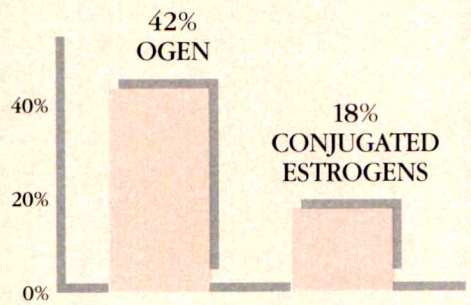
Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
—Title of article
—Full name(s) and affiliations of author(s)
—Author to whom correspondence is to be sent
—Reprint request line or line stating reprints not available
—Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material



Withdrawal Bleeding in the ERT Patient:

Necessity or Nuisance?

- **To protect against the endometrial hyperplasia** that may result from continuous, unopposed estrogen administration, cyclical estrogen/progestogen therapy is often given.[1] But this may induce withdrawal bleeding, unacceptable to many patients.

- **Progestogen initiates bleeding** only when the endometrial mucosa is stimulated to the threshold level by the estrogen.

More women on Ogen free of withdrawal bleeding[2]

Patients received Ogen 1.25 (n=45) or conjugated equine estrogens 0.625 mg (n=50) days 1-24 over 3 monthly cycles. All patients also received a progestational agent days 15-24. Adapted from Wren, et al.[2]

- Studies[2,3] suggest that Ogen® (estropipate) produces less withdrawal bleeding...*at doses that effectively protect patients from symptoms of menopause.*

7013807R

Abbott Pharmaceuticals, Inc.

OGEN® (estropipate) Induces Less Withdrawal Bleeding

OGEN®
(estropipate)

Only estrone. Identical to the body's own.

OGEN®

ESTROPIPATE TABLETS, USP

Tablets

WARNING:

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. OGEN SHOULD NOT BE USED DURING PREGNANCY.

According to some investigators, the use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. Studies have reported that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. In one of these studies, this risk was estimated as not greater than 4 per 1000 exposures. Furthermore, there are reports that a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these reported changes are histologically benign, the investigators have not determined whether they are precursors of adenocarcinoma.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies in the offspring, including heart defects and limb reduction defects. One case control study estimated a 4.7 fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. OGEN has not been studied for these uses, and therefore should not be used during pregnancy. There is no evidence from well controlled studies that progestogens are effective for these uses.

If OGEN (estropipate tablets) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the question of continuation of the pregnancy should be addressed.

INDICATIONS AND USAGE

The cyclic administration of OGEN (estropipate tablets) is indicated for the treatment of estrogen deficiency associated with (See "DOSAGE AND ADMINISTRATION" section):

1. Moderate to severe *vasomotor* symptoms of menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.)
2. Atrophic vaginitis.
3. Kraurosis vulvae.
4. Female hypogonadism.
5. Female castration.
6. Primary ovarian failure.

OGEN (ESTROPIPATE TABLETS) HAS NOT BEEN TESTED FOR EFFICACY FOR ANY PURPOSE DURING PREGNANCY. SINCE ITS EFFECT UPON THE FETUS IS UNKNOWN, IT CANNOT BE RECOMMENDED FOR ANY CONDITION DURING PREGNANCY (SEE BOXED WARNING).

CONTRAINDICATIONS

OGEN should not be used in women with any of the following conditions:

1. Known or suspected cancer of the breast.
2. Known or suspected estrogen-dependent neoplasia.
3. OGEN may cause fetal harm when administered to a pregnant woman. OGEN is contraindicated in women who are or may become pregnant (See Boxed Warning).
4. Undiagnosed abnormal genital bleeding.
5. Active thrombophlebitis or thromboembolic disorders.
6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. *Induction of malignant neoplasms.* Long-term continuous administration of natural and synthetic estrogens in certain animal species has been reported by some investigators to increase the frequency of carcinomas of the breast, cervix, vagina, and liver. There is now evidence that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning).

At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. Therefore, caution should be exercised when administering estrogens to women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. Careful breast examinations should be performed periodically.

2. *Gall bladder disease.* A recent study has reported a 2 to 3-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens, similar to the 2-fold increase previously noted in users of oral contraceptives. In the case of oral contraceptives, the increased risk appeared after two years of use.

3. *Effects similar to those caused by estrogen-progestogen oral contraceptives.* There are several serious adverse effects of oral contraceptives, most of which have not, up to now, been documented as consequences of postmenopausal estrogen therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women. It would be expected that the larger doses of estrogen used to treat postpartum breast engorgement would be more likely to result in these adverse effects, and, in fact, it has been shown that there is an increased risk of thrombosis in women receiving estrogens for postpartum breast engorgement.

a. *Thromboembolic disease.* It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism; it should also be discontinued during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. *Hepatic adenoma.* Benign hepatic adenomas appear to be associated with the use of oral contraceptives. Although benign, and rare, these may rupture and cause death through intraabdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations but should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The relationship of this malignancy to these drugs is not known at this time.

c. *Elevated blood pressure.* Increased blood pressure is not uncommon in women using oral contraceptives. There is now a report that this may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used.

d. *Glucose tolerance.* A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. *Hypercalcemia.* Administration of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

PRECAUTIONS

A. General Precautions.

1. A complete medical and family history should be taken prior to the initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.
2. Fluid retention — Estrogens may cause some degree of fluid retention. Therefore, patients with conditions such as epilepsy, migraine, and cardiac or renal dysfunction, which might be influenced by this factor, require careful observation.
3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc.
4. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.
5. Preexisting uterine leiomyomata may increase in size during estrogen use.
6. The pathologist should be advised of the patient's use of estrogen therapy when relevant specimens are submitted.
7. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving estrogen-containing oral contraceptive therapy. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.
8. Estrogens may be poorly metabolized in patients with impaired liver function and they should be administered with caution in such patients.
9. Because estrogens influence the metabolism of calcium and phosphorus, they should be used with caution in patients with metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency.

B. Information for the Patient. See text of Patient Package Insert which appears after PHYSICIAN REFERENCES.

C. Drug Interactions. The concomitant use of any drugs which can induce hepatic microsomal enzymes with estrogens may produce estrogen levels which are lower than would be expected from the dose of estrogen administered.

The use of *broad spectrum antibiotics* which profoundly effect intestinal flora may influence the absorption of steroidal compounds including the estrogens.

Diabetics receiving *insulin* may have increased insulin requirements when receiving estrogens.

Laboratory Test Interference. Certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following similar changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.
b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.
d. Abnormal glucose tolerance test results.
e. Decreased pregnanediol excretion.
f. Reduced response to metyrapone test.
g. Reduced serum folate concentration.
h. Increased serum triglyceride and phospholipid concentration.

D. Carcinogenesis. Studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods (see Boxed Warning). At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. (See "WARNINGS" section.)

E. Pregnancy. Pregnancy Category X. See "CONTRAINDICATIONS" section and Boxed Warning.

F. Nursing Mothers. Estrogens have been reported to be excreted in human breast milk. Caution should be exercised when OGEN is administered to a nursing woman.

G. Pediatric Use. Because of the effects of estrogens on epiphyseal closure, they should be used judiciously in young patients in whom bone growth is not complete.

ADVERSE REACTIONS

(See Warnings regarding reports of possible induction of neoplasia, unknown effects upon the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions in decreasing order of severity within each category have been reported with estrogenic therapy, including oral contraceptives:

1. *Genitourinary system.*
Increase in size of uterine fibromyomata.
Vaginal candidiasis.
Cystitis-like syndrome.
Dysmenorrhea.
Amenorrhea during and after treatment.
Change in cervical eversion and in degree of cervical secretion.
Breakthrough bleeding, spotting, change in menstrual flow.
Premenstrual-like syndrome.
2. *Breast.*
Tenderness, enlargement, secretion.
3. *Gastrointestinal.*
Cholestatic jaundice.
Vomiting, nausea.
Abdominal cramps, bloating.
4. *Skin.*
Hemorrhagic eruption.
Erythema nodosum.
Erythema multiforme.
Hirsutism.
Chloasma or melasma which may persist when drug is discontinued.
Loss of scalp hair.
5. *Eyes.*
Steepening of corneal curvature.
Intolerance to contact lenses.
6. *CNS.*
Chorea.
Mental depression.
Migraine, dizziness, headache.
7. *Miscellaneous.*
Aggravation of porphyria.
Edema.
Reduced carbohydrate tolerance.
Increase or decrease in weight.
Changes in libido.

OVERDOSAGE

Numerous reports of ingestion of large doses of estrogen-containing oral contraceptives by young children indicate that serious ill effects do not occur. Overdosage of estrogen may cause nausea and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION

1. *Given cyclically for short-term use:*

For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., 3 weeks on and 1 week off).

Attempts to discontinue or taper medication should be made at 3 to 6 month intervals.

Usual dosage ranges:

Vasomotor symptoms —One OGEN .625 (estropipate) Tablet to one OGEN 5 Tablet per day. The lowest dose that will control symptoms should be chosen. If the patient has not menstruated within the last two months or more, cyclic administration is started arbitrarily. If the patient is menstruating, cyclic administration is started on day 5 of bleeding.

Atrophic vaginitis and kraurosis vulvae — One OGEN .625 Tablet to one OGEN 5 Tablet daily, depending upon the tissue response of the individual patient. The lowest dose that will control symptoms should be chosen. Administer cyclically.

2. *Given cyclically:*

Female hypogonadism; female castration; primary ovarian failure.

Usual dosage ranges:

Female hypogonadism — A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. The lowest dose that will control symptoms should be chosen. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium. If satisfactory withdrawal bleeding does not occur, an oral progestogen may be given in addition to estrogen during the third week of the cycle.

Female castration and primary ovarian failure —A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. Adjust dosage upward or downward according to severity of symptoms and response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED

OGEN (estropipate tablets, USP) is supplied as OGEN .625 (0.75 mg estropipate), yellow tablets, **NDC** 0074-3943-04; OGEN 1.25 (1.5 mg estropipate), peach-colored tablets, **NDC** 0074-3946-04; OGEN 2.5 (3 mg estropipate), blue tablets, **NDC** 0074-3951-04; and OGEN 5 (6 mg estropipate), light green tablets, **NDC** 0074-3958-13. Tablets of all four dosage levels are standardized to provide uniform estrone activity and are grooved (Divide-Tab®) to provide dosage flexibility. All tablet sizes of OGEN are available in bottles of 100.

CLINICAL SECTION

Clinical Opinion

When does a statistical fact become an ethical imperative?

Richard K. Silver, M.D., and John Minogue, D.Min.

Chicago, Illinois

Trial of labor is a safe and effective management alternative but remains underused in current clinical practice. To explore whether this underuse is justified, decision analysis is developed to compare a trial of labor with elective repeat cesarean section. With the use of available probability estimates and outcome scoring based on a survey of perinatologists, decision analysis identifies trial of labor as superior to elective repeat cesarean section for both the mother and the neonate. Going beyond the simple comparisons of management options and outcomes, the ethical implications of such results are discussed in terms of "utility ethics," "informed consent," and "universal equality." Such considerations suggest that there is a professional (ethical) responsibility to increase the application of trial of labor. (AM J OBSTET GYNECOL 1987;157:229-33.)

Key words: Trial of labor, decision analysis, utilitarianism

Many claim that what separates a "profession" from a job is the adherence to a set of values and ethical standards. If the profession of medicine is to be something more than the application of basically successful techniques, then that something more will be found in the intangibles of commitment to the ethical principles that guide the practitioner in his/her employment of those techniques. This discussion will attempt to assess trial of labor and the professional/ethical implications of its use as compared to repeat cesarean section. The choice of treatment options will be considered in relation to the principles of "utility ethics," "informed consent," and "universal equality."

Vaginal delivery after a previous cesarean section is considered a contemporary practice alternative. Despite numerous publications confirming the efficacy and safety of this approach, as well as support issued from our specialty,[1] trial of labor remains underused in most medical centers. Even if this alternative is offered by obstetricians, a minority of the eligible patients elect a labor trial, and if oxytocin is disallowed,[2] attempts at vaginal delivery may be abandoned prematurely. The presumed safety of cesarean section, the fear of uterine rupture, and patient preference are among the factors that contribute to the selection of elective surgery over trial of labor. By conservative estimate, if trial of labor is offered at a particular institution, at least half of the repeat cesarean sections performed could be avoided.

In clinical terms, decision analysis is used to identify the treatment plan that provides the best outcome for a majority of patients with a particular condition. Once the best plan is discovered, criteria for a standard of practice may be established. The objectivity of this approach (with the use of both probability estimates and a mathematical model) is appealing when compared with conclusions based on intuition, personal experience, or retrospective review. A risk-benefit assessment may be particularly useful when a prospective study of treatment alternatives is unavailable. Ethically, this type of analysis is known as utilitarianism, whose basic criterion is "do that which promotes the most happiness for the most people."

Shy et al.[3] derived probabilities related to trial of labor and repeat cesarean section. With these figures and a hypothetical cohort of eligible patients, they ap-

Table I. Outcome probabilities* for repeat cesarean section and trial of labor

Outcome	*Probability*
Maternal death with vaginal delivery	0.00008
Maternal death with RCS	0.0004
Maternal death with uterine rupture	0.02
Perinatal death with elective term RCS	0.005
Perinatal death with iatrogenic preterm RCS	0.085
Perinatal death with intrapartum RCS	0.008
Perinatal death with vaginal delivery	0.013
Perinatal death with uterine rupture	0.119
Preterm delivery with elective RCS	0.054
Antepartum uterine rupture	0.0019
Intrapartum uterine rupture	0.007
Hysterectomy required after uterine rupture	0.72†
Spontaneous labor before elective RCS	0.20
Failed TOL and indicated RCS	0.33

RCS = Repeat cesarean section; TOL = trial of labor.
*Probabilities adapted from Shy et al.[3]
†Probability derived from references 8 to 10.

plied decision analysis and concluded that maternal and perinatal mortality were similar for either treatment alternative. Although this conclusion might argue in favor of trial of labor, some may view the glass as half empty. If there is no difference in outcome as measured in units of mortality, why not continue with the practice of elective repeat cesarean section? The obvious answer is that there is more to this health care issue than risk of death. A critical concern is the contribution of repeat cesarean section to the "epidemic" of abdominal delivery.[4] Prolonged hospitalization and recovery, surgical morbidity, the need for cesarean section in subsequent pregnancies, and additional cost are examples of other important concerns. Decision analysis provides a mechanism for including the effect of these types of outcome variables along with mortality estimates.

Material and methods

Assessment of accurate probabilities and assignment of relative value scores are the two prerequisites for decision analysis. We used the derived probabilities for trial of labor–related outcomes provided by Shy et al.,[3] as summarized in Table I. In order to include measures of morbidity in addition to mortality estimates, we incorporated nine other complications into our decision trees (Table II). To assign utility scores for all complications, relative rankings and deductions were solicited from eight board-eligible or board-certified perinatologists (three female, five male, excluding the author). These physicians were instructed to rank 11 outcomes in descending order of severity and then to deduct up to 100 points for each item (Table II). The most serious outcome would be ranked first and assigned the largest deduction. Their responses were tabulated and the mean score for each outcome was derived. Next, 100 points were arbitrarily awarded to each outcome pathway of the decision tree from which appropriate deductions were taken. For instance, a woman attempting a trial of labor, who suffers a uterine rupture during labor but is delivered of a healthy infant and survives the operation without the need for hysterectomy, would incur the following deductions: 59 points for intrapartum rupture, 19 points for prolonged hospitalization, 18 points for any future cesarean section, 18 points for additional cost, 10 points for failed trial of labor, 6 points for discomfort, and 3 points for inconvenience (total score of 100 to 133 or −33). Utility scores for each pathway are listed on the right of Figs. 1 and 2. In these figures, the probabilities (in parentheses) are multiplied by the utility scores and the products are summed (from right to left) at each branch of the tree. The management alternative with the greatest score has the highest utility (that is, statistically provides the most happiness to the most patients) and is therefore the clinical approach of choice.

Decision analysis of this type is not designed to function as a model for clinical management (for example, a left-to-right reading of the decision tree). Such analysis would require sensitivity testing of every probability and deletion of all insensitive nodes. In contrast, the approach here is validated only at its end point (in this case, the final score).

Comment

Decision analysis. The higher score for trial of labor (67.3) indicates that when it is compared with elective repeat cesarean section (38.8), this alternative provides the best outcome for mother, baby, and society. Admittedly, the assigned utility scores are subjective. Although the rank order may be agreeable to most clinicians (as was the case for the rankings in our survey; Table II, Rank Agreement column), the specific point assignments may vary among physicians, patients, and other health care providers. We chose a physician source for utility scores because it is from a chiefly medical perspective that counseling is accomplished. With the recognition that patient values may be different, relevant nonmedical concerns (anxiety of awaiting labor, discomfort in labor, and disappointment of a failed trial of labor) were also included in the model and assigned utility scores.

Another possible area of disagreement involves the selection and accuracy of assigned probabilities. To address this criticism, sensitivity testing at any probability node can be performed. Two examples are illustrated as follows. A particular hospital experiences only a 50% vaginal delivery rate among their trial of labor patients. Substitution of this rate in Fig. 2 would reduce the total score to 56.5, while the score for repeat cesarean section would remain 38.8. Similarly, if an exaggerated rate of

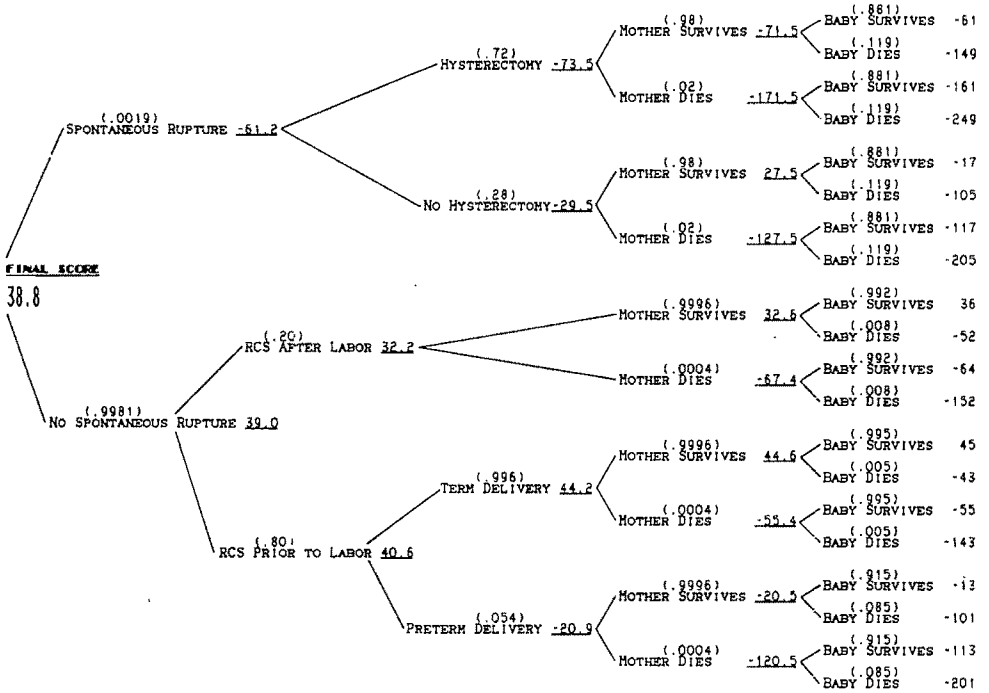

Fig. 1. Decision analysis for repeat cesarean section. Probabilities are in parentheses and subtotal scores are underlined. *RCS* = Repeat cesarean section.

Table II. Assignment of utility scores to maternal and perinatal outcomes

Outcomes listed by rank order	*Mean utility score (± SD)*	*Range*	*Rank agreement**
1. Maternal death	100 ± 0	—	8
2. Neonatal death	88 ± 16	50-100	8
3. Need for hysterectomy	62 ± 16	40-95	7
4. Uterine rupture	59 ± 14	40-80	8
5. Iatrogenic prematurity	58 ± 22	25-90	4
6. Need for future repeat cesarean section	18 ± 10	5-40	6
7. Prolonged hospitalization and recovery	19 ± 10	5-40	5
8. Additional cost	18 ± 8	0-30	7
9. Failed trial of labor	10 ± 6	0-19	7
10. Discomfort of labor	6 ± 9	0-30	7
11. Inconvenience of awaiting labor	3 ± 4	0-10	8

*Number of respondents (out of eight) agreeing with ranking plus or minus one order of rank.

intrapartum uterine rupture were assumed (for example, 5%), the trial of labor score would be reduced to 61.7. In both these instances, the trial of labor score remains higher than its repeat cesarean section counterpart and is therefore the better alternative. In fact, to support the contention that elective repeat cesarean section and trial of labor are equivalent alternatives, one would need to artificially reduce the trial of labor success rate to <25% or increase the intrapartum risk for uterine rupture to >20%.

Even if decision analysis selects trial of labor, wide implementation of this alternative would be difficult in light of the currently recommended trial of labor prerequisites. These include 24-hour blood banking and 30-minute operative start-up time. Admittedly, management of complete uterine dehiscence requires emergency anesthetic services. However, uterine rupture may occur as often before labor as during labor and even occurs among patients without a previous uterine incision. In fact, a recent review by Finley and Gibbs[5] uncovered similar rates of emergent operation for patients with and without a previous cesarean section, implying no greater risk for trial of labor candidates.

Ethical considerations. To shift from numbers to their professional-ethical implications is a fairly straightforward transition if utilitarianism is used. Risk-benefit analysis is born and bred in the American tradition. Using the principles of utility to decide the right

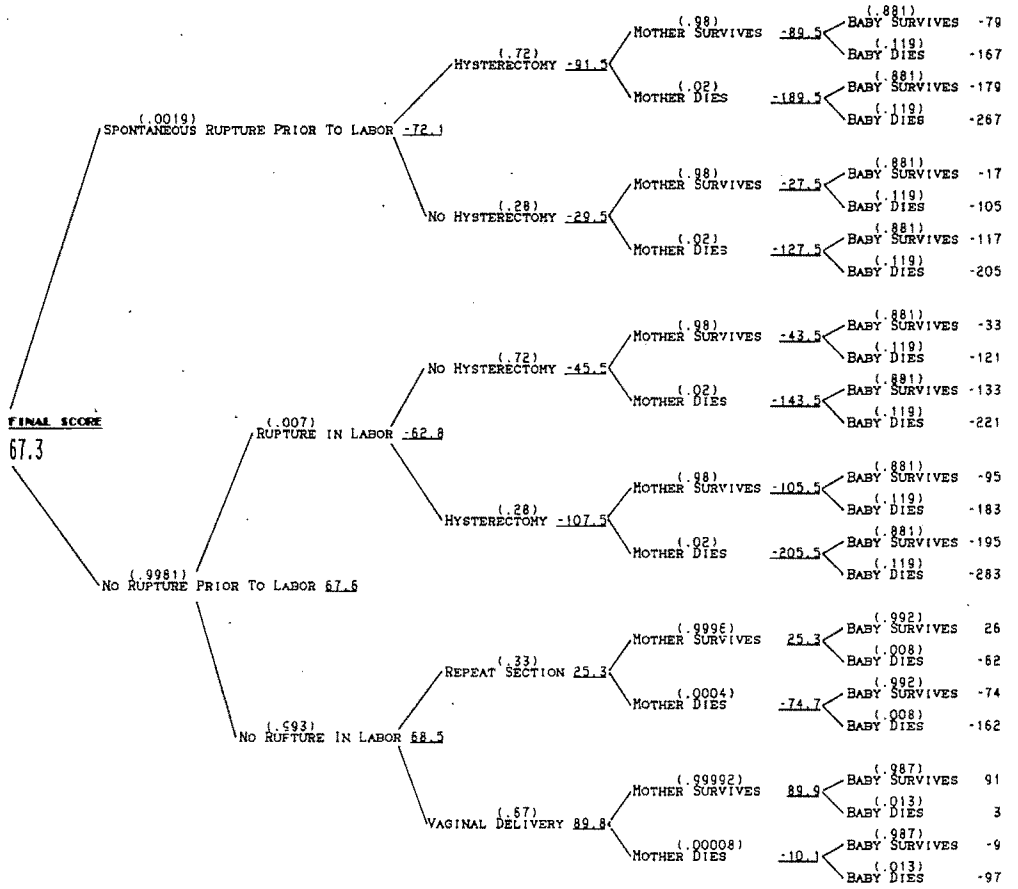

Fig. 2. Decision analysis for trial of labor. Probabilities are in parentheses and subtotal scores are underlined.

and good thing to do runs deep in the American way of thinking; it is also a skill honed to a fine edge in medical training. After all, what is a more congruent way of deciding which course of medical intervention to follow than a risk-benefit analysis? The congruence between the practice of medicine and utilitarianism seems to be a match made in heaven. The development and reliance of modern clinical medicine on statistical analysis of outcome provide utility ethics with the actuarials it needs to derive the outcome-based decision trees. In return, utility ethics provides modern medicine with a license to practice a profession (on the presumption that what distinguishes a profession from a job is a code of ethics that is intrinsic to its functioning).

In regard to the case at hand, using simply utilitarianism, it should be argued that anything other than trial of labor after a previous cesarean section is unethical because the utility scores demonstrate that the trial of labor option holds the best outcome for both the individual patient and the patient population taken as a group. Perhaps the appeal and strength of utilitarian argumentation lie in its focus on outcomes. Although good intentions are nice, for better or worse, it is by results that the medical profession is often judged. What better way to justify a treatment option than to show its positive results.

There are those who are less than euphoric about the relationship between utility ethics and medicine. Two internal problems with the utilitarian system are pointed to: First, it claims objectivity based on a quantification that is really subjective; second, the system has no ability to critically reject any given means, as long as it achieves the most good for the most people. A clinical practice based only on outcome without any commitment to principles would be in danger of subjecting some patients to grave hardship so that most of the patients could benefit. It could easily ignore an equally cherished value and ethical commitment among medical practitioners: the patient's right of autonomy, as safeguarded by the principle of informed consent. The point of these critiques is not to dismiss outcome analysis as a reasonable and ethical criterion for medical decision; it is rather to argue that utilitarianism can neither be the sole criterion of ethical judgment nor be claimed as a purely objective standard. Thus, even though a utility analysis is compelling in regard to trial of labor, perhaps it is not the whole story. The right to

informed consent must be included in any discussion of patient counseling.

Informed consent finds its roots in several considerations. Some would see the principle of informed consent deriving from the simple notion that those who bear the consequences should have the major say in what is to be done. Others see this principle as derived from the very nature of what it is to be human, since to be human is to be responsible and self-determining. Still others would derive the principle of informed consent from a legally granted constitutional right based on social contract. Despite the drastically diverse foundations, each of these reasoning processes would argue that no matter what the outcome, a patient must in principle be informed and consent to a treatment plan. In the extreme, this ethic would argue that the patient has a right to refuse a given treatment, even though such a treatment provides a better outcome than withholding it. This ethic is clearly operative in medicine today.

In relationship to trial of labor, the principle of informed consent would provide that the patient be: (1) accurately informed concerning treatment options, (2) apprised of the specific advantages and disadvantages of trial of labor, and (3) allowed the freedom to determine a reasonable treatment alternative without undue external influence. After being approached to obtain informed consent for trial of labor, 140 of 247 women chose elective repeat cesarean section.[6] Such a low selection rate for a clearly better option by decision analysis might suggest that clear information is not being provided, that inadvertent coercion might be occurring, or that other significant factors influencing patient choice have not been included in our utility model. From the perspective of informed consent, it would be unethical to sway the patients' decisions by use of either unclear information or manipulative images (for example, describing abdominal delivery as a procedure that is safe, convenient, and fairly pain-free while describing labor as long and painful with many uncertainties). Clearly, our own biases in regard to delivery options are going to influence the patients' choices. In fairness to the principle of informed consent, we might make some attempt to eliminate the obvious coercions and balance for the more subtle influences our biases may bring about. Certainly, by the same principle, the patient's concerns must be put into perspective relative to the medical risks of the proposed choices. Specifically, the convenience of a known due date or the avoidance of labor needs to be considered in the context of the risks of elective operation. Although informed consent would not dictate a labor trial, it certainly would be considered unethical if the patient were not presented with correct information in a noncoercive manner.

There are certain types of ethical considerations that are even more restrictive in relation to what options the patient and physician have. Such an ethic is proposed by Immanuel Kant in his book *Fundamental Principles of the Methaphysics of Morals.* His criteria of ethical practice would be derived from the categorical imperative basically stated as: Do only that which you can will to be a universal law.[7] Further, only duty is a fitting motive, for any other motive would be self-serving and less than ethical. Such a system seeks to bring about a universalization of conduct based on principle. Following this type of ethic, if the physician was truly persuaded by the statistics that a trial of labor is best for the patient, then it would be his/her duty to offer only this alternative. This would transcend even the patient's right to choose, since in this system duty and what is right supersede freedom. Though somewhat lockstep, Kant's in-principled ethic has the merit of treating all patients equally and demanding of the physician his/her best effort to ascertain what is best for his/her patient.

In summary, we are obviously persuaded as to the benefit of a labor trial for those patients meeting appropriate guidelines. The arguments presented here favor trial of labor. Not only the numbers but the principles seem to argue for this management option. Certainly what is in the interest of the individual patient is probably best assessed within the personal relationship between the patient and physician. Statistics and general principles cannot overshadow the important variables that make up such relationships. However, as a profession we have an obligation to continually assess, by reasonable standards, what does serve the best interest of our patients.

Antithyroid drugs: To breast-feed or not to breast-feed

David S. Cooper, M.D.
Baltimore, Maryland

Historically, women taking antithyroid drugs generally have not been permitted to breast-feed. However, recent studies suggest that infants exposed to the small amounts of antithyroid drugs in breast milk experience no change in thyroid function. Propylthiouracil is the drug of choice in this situation, since it does not cross membranes readily, and milk concentrations are therefore quite low. However, methimazole in low dosages might be used if the infant's thyroid status was monitored at frequent intervals. (Am J Obstet Gynecol 1987;157:234-5.)

Key words: Breast-feeding, propylthiouracil, methimazole

Thyrotoxicosis resulting from Graves' disease occurs commonly enough during pregnancy (one in every 500 to 1000) to warrant periodic review articles[1] and continued research regarding its optimal management.[2, 3] Antithyroid drugs are accepted as the treatment of choice for most patients and have generally been safe and effective therapy for both mother and fetus.[1] However, the question of how to manage the hyperthyroidism after delivery, particularly with respect to breast-feeding, has not been addressed in any comprehensive way in the literature. It is the purpose of this brief review to summarize the available data and formulate specific recommendations regarding antithyroid drugs and the nursing mother.

The problem of antithyroid drugs in breast milk was originally studied by Williams et al.[4] in 1944, with the first antithyroid drug thiouracil. It was demonstrated by a relatively crude nonspecific colorimetric assay that thiouracil concentrations in milk were approximately threefold higher than serum concentrations. Although this drug ceased to be used after 1946, the data on thiouracil levels in milk were extended by inference to include propylthiouracil (introduced in 1946) and methimazole (introduced in 1949). Women taking either of these drugs were advised by most physicians not to breast-feed[5, 6] for fear of causing hypothyroidism in the infant.

The issue was rekindled in 1979 by Low et al.,[7] who administered ^{35}S propylthiouracil to one lactating patient and found that the accumulation of ^{35}S propylthiouracil in milk (measured simply as ^{35}S activity) represented only 0.077% of the administered propylthiouracil dosage over 24 hours. With the subsequent development of sensitive and specific assays for the antithyroid drugs, a number of recent studies have examined this question in more detail. With a sensitive spectrophotometric technique, Kampmann et al.[8] measured propylthiouracil concentrations in the milk of nine lactating women after the oral administration of 400 mg. Only 0.025% of the total dosage was excreted in the milk over 4 hours (i.e., 100 μg). The authors[8] also monitored thyroid function in one infant whose mother was taking 200 to 300 mg propylthiouracil daily and found no change in thyroid function tests, including serum thyroid-stimulating hormone. Since this article, there have been reports[9-11] of a total of six additional infants whose thyroid function tests remained normal while their mothers were taking propylthiouracil in dosages ranging from 125 to 300 mg daily.

Although these limited data on propylthiouracil are reassuring, studies of methimazole (and its close relative carbimazole) are less clear-cut. There are three reports[12-14] involving a total of 10 women, in which methimazole or carbimazole excretion in breast milk was examined. Regardless of the methodology used to measure methimazole, all three studies indicate that methimazole enters the milk freely from the serum compartment, with milk to plasma drug ratios equaling 1. Calculations have been performed showing that an infant might receive as much as 70 μg after a 40 mg dose of methimazole, an amount that could theoretically affect the baby's thyroid function. Nevertheless, Lamberg et al.[9] recently reported on 12 infants whose mothers were treated with the methimazole derivative, carbimazole, in dosages ranging from 5 to 15 mg daily (equal to 3.3 to 10 mg methimazole). All 12 infants had normal thyroid function (including thyroid-stimulating hormone) at 4, 14, and 21 days, and two infants remained normal at 3 and 4 months of age with continued breast-feeding. Thus, at very small dosages, methimazole is probably also a safe drug for the nursing mother.

The theoretical reasons that methimazole but not propylthiouracil would be present in significant concentrations in milk have been reviewed.[10] In brief, the

most likely explanation is that propylthiouracil is ionized at physiologic pH and is also heavily protein bound (80%), preventing its diffusion across membranes, whereas methimazole is neither ionized nor bound to serum proteins.

The available data suggest that infants exposed to small quantities of antithyroid drugs do not become hypothyroid. On the basis of this assumption, the following recommendations can be made. Any mother who requires antithyroid drug therapy in the postpartum period and who wishes to breast-feed should be allowed to do so. However, the potential risk of neonatal hypothyroidism exists, and the necessity for monitoring the neonate's thyroid function should be made clear to the mother; a serum thyroxine and thyroid stimulating hormone determination every 2 to 4 weeks would be reasonable. Although it has not been reported, the possibility that the infant could have an idiosyncratic reaction (e.g., fever, rash, agranulocytosis) to the drug should also be noted. Although infants have done well after exposure to both propylthiouracil and small dosages of methimazole, propylthiouracil remains the drug of choice because of its lower potency and lower breast milk concentration. However, if the mother were allergic to propylthiouracil, methimazole in dosages of $\leq$10 mg might be used if the infant's thyroid functions were monitored more intensively, at weekly or biweekly intervals.

The use of fetal biophysical profile improves pregnancy outcome in premature rupture of the membranes

Anthony M. Vintzileos, M.D., Roy Bors-Koefoed, M.D., James F. Pelegano, M.D., Winston A. Campbell, M.D., John F. Rodis, M.D., David J. Nochimson, M.D., and Vasilios G. Kontopoulos, M.D.

Farmington, Connecticut

A protocol using daily fetal biophysical assessment was applied in 73 consecutive patients with premature rupture of the membranes and no clinical signs of infection or labor. A persistently low biophysical score (7 or less on two examinations 2 hours apart) in the presence of a nonreactive nonstress test and absence of fetal breathing was used as an indication for delivery. Measures of pregnancy outcome included the presence of amnionitis or neonatal infection. The outcome of pregnancy in this group of patients was compared with the outcomes of two historic groups: one managed conservatively (control group) and the other managed with amniocentesis on admission to the hospital (amniocentesis group). Infection outcome, maternal as well as neonatal, and low 5-minute Apgar scores were significantly less in the study than in the control group. The frequency of neonatal sepsis was significantly less in the study than in the amniocentesis group. These data suggest that management of premature rupture of the membranes with daily fetal biophysical profiles improves pregnancy outcome by reducing the incidence of maternal and neonatal infection. (Am J Obstet Gynecol 1987;157:236-40.)

The fetal biophysical profile (nonstress test, fetal breathing movements, fetal movements, fetal tone, amniotic fluid volume, and placental grading) has been described previously by us as an early predictor of fetal infection in patients with premature rupture of the membranes and no clinical signs of infection or labor. In that report patients whose last biophysical assessment was within 24 hours of delivery had an infection rate of 93.7% when the biophysical profile score was 7 or less, whereas the frequency of infection with a biophysical profile score of 8 or more was only 2.7%; in that study the fetal biophysical profile results were not used for management.[1] Subsequently, in another report the authors described the efficacy of a protocol using amniocentesis on admission in the management of patients with premature rupture of the membranes; this protocol was found to reduce the frequency of clinical amnionitis and low 5-minute Apgar scores but did not reduce the frequency of neonatal infection, low 1-minute Apgar scores, and perinatal death rate.[2]

The purpose of the present study was to evaluate the efficacy of a protocol using daily fetal biophysical profile assessment in the management of patients with premature rupture of the membranes and no clinical signs of infection or labor. The pregnancy outcome of the study group, as determined by the development of maternal or neonatal infection, was compared with the outcomes of the two historic groups: the first managed conservatively (control group) and the second managed with amniocentesis on admission to the hospital (amniocentesis group). Measures of outcome of infection included the presence of clinical amnionitis, possible neonatal sepsis, and neonatal sepsis.

Material and methods

The study group included 73 consecutive patients with premature spontaneous rupture of the membranes. The majority of patients (71 of 73) were transferred to the University of Connecticut Health Center because of preterm premature rupture of the membranes. The study group consisted of patients admitted to the hospital during the period of August 1, 1985,

through November 15, 1986. The historic control group (73 patients) consisted of patients with premature rupture of the membranes admitted during the period of July 1, 1983, through June 30, 1984,[1] and the amniocentesis group (73 patients) involved patients admitted consecutively during the period of July 1, 1984, through April 30, 1985.[2] All three groups involved singleton pregnancies and gestational ages of 25 weeks or greater with premature rupture of the membranes and no labor. Patients with signs of labor, chorioamnionitis, bleeding, or fetal distress on admission were excluded. The prior use of tocolysis and the presence of other complicating factors (such as pregnancy-induced hypertension, intrauterine growth retardation, and diabetes mellitus) were also exclusion criteria. The inclusion and exclusion criteria were the same for the three groups.

In all patients, rupture of the membranes was diagnosed by sterile speculum examination with pooled fluid, ferning, and alkaline pH determination (Nitrazine Paper). Bimanual pelvic examinations were not performed unless the patients were believed to be in active labor or a decision had been made to induce labor. On admission to the hospital, maternal vital signs were recorded and electronic fetal heart rate monitoring was used to detect signs of fetal distress and document any uterine activity. If there was no evidence of labor, fetal distress, or infection, an ultrasonographic evaluation was performed for confirmation of the gestational age and determination of the fetal biophysical profile. The ultrasonographic evaluation was performed by means of a linear-array real-time ultrasonographic method (General Electric SRT 2600, Wilmington, Massachusetts) equipped with a 3.5 MHz transducer. Real-time scanning consisted of a maximum 30-minute observation period during which fetal movements and fetal breathing movements were counted and fetal tone, amniotic fluid volume, and placental grading were estimated. Each biophysical variable was scored as 2, 1, or 0 according to the criteria cited in a previous study.[3] The maximal score was 12 and the minimal 0. In the historic control group the results of the fetal biophysical profile were not used for management. In the amniocentesis group immediately after the ultrasonographic examination, an amniocentesis under direct ultrasonic guidance was performed and the fluid was sent immediately for Gram staining and cultures. In the study group an abnormal biophysical assessment was used as an indication for delivery (biophysical score of 7 or less on two examinations 2 hours apart in the presence of a nonreactive nonstress test and absence of fetal breathing).

All three groups were observed in the hospital and were managed conservatively with bed rest and bathroom privileges. Corticosteroid therapy was administered in the majority of patients (Table I). Temperatures were taken four times a day and white blood cell counts were performed daily. Antibiotics were administered to the mother only after the cord was clamped. In the study group the fetal biophysical profile determinations were repeated every 24 hours if patients remained undelivered. Indications for delivery in the control group included labor, clinical amnionitis, persistent spontaneous variable decelerations (moderate to severe), or gestational age >37 weeks after a 24-hour period of observation. The results of the fetal biophysical profile were not used in the management of the control group. Indications for delivery in the amniocentesis group were the same as for the control group in addition to a positive Gram stain or culture of the obtained amniotic fluid and a lecithin:sphingomyelin ratio of 2 or greater. Indications for delivery in the study group were the same as for the control group in addition to a persistently low fetal biophysical score

Table II. Comparison of outcome of pregnancy between the three groups

*Overall infectious outcome includes patients with infection (mother or neonate), some of whom had more than one diagnosis.
†Overall neonatal infection combines neonates with possible neonatal sepsis and neonatal sepsis.

(7 or less on two examinations 2 hours apart in the presence of a nonreactive nonstress test and absence of fetal breathing).

On admission to the neonatal intensive care unit, cultures were performed in all infants (blood, urine, cerebrospinal fluid, trachea, nasogastric, and external ear). All neonates received prophylactic antibiotics that were discontinued when the cultures demonstrated no growth. When neonatal sepsis or possible neonatal sepsis was diagnosed, the antibiotics were continued for approximately 7 to 10 days. The diagnosis of clinical amnionitis, possible neonatal sepsis, and neonatal sepsis was based on previously described criteria.[1-4] The pregnancy outcome of the study group, as determined by the development of maternal or neonatal infection, was compared with the outcomes of the two historic groups: the first managed conservatively (control group) and the second managed with amniocentesis on admission (amniocentesis group). Postdelivery data collection included Apgar scores, cord blood pH (umbilical artery and vein), neonatal septic workup, and perinatal deaths.

Statistical analysis was performed by the χ^2, Fisher's exact, or Student t test when appropriate.

Results

The study group included 73 consecutive patients with premature rupture of the membranes. A total of 231 fetal biophysical profiles were done in these 73 patients (3.1 per patient). Twenty examinations were the most performed on one patient. The mean gestational age on admission to the hospital was 31.4 weeks (range 25 to 38 weeks) and the mean birth weight (±2 SDs) was 1768 gm (±976 gm). The cesarean section rate was 48% (35 of 73).

The characteristics of the three groups on admission are shown in Table I. There were no differences between the three groups in terms of mean gestational age, preterm gestations, corticosteroid administration, birth weight, and distribution of amniotic fluid volume. Because the degree of oligohydramnios has been described as a risk factor for infectious morbidity in patients with premature rupture of the membranes,[4,5] all three groups were also compared according to amniotic fluid distribution but no differences were found. The number of fetuses with low biophysical scores (7 or less) was not different between the study and control group.

The comparison of outcomes of pregnancy between the three groups is shown in Table II. Compared with the control group, the study group was found to have a significantly lower frequency of overall infectious outcome (number of patients who developed infection; $p < 0.005$), amnionitis ($p < 0.01$), and 5-mminute Apgar scores ($p < 0.005$). The p values for possible neonatal sepsis and neonatal sepsis were 0.09 and 0.06, respectively. When possible neonatal sepsis and neonatal sepsis were combined (overall neonatal infection) the difference became statistically significant ($p < 0.005$). There were no differences between the study and control groups in terms of 1-minute Apgar scores <7, umbilical cord pH (artery and vein), and perinatal death rate. Compared with the amniocentesis group, the study group was found to have a significantly lower frequency of neonatal sepsis ($p < 0.05$). The overall neonatal infection was also significantly less in the study group ($p < 0.005$). There were no differences between

the study and amniocentesis groups in terms of overall infectious outcome (number of patients who developed infection), amnionitis, possible neonatal sepsis, Apgar scores, umbilical cord pH (artery and vein), and perinatal death rate.

Eight (10.9%) patients developed infection in the study group. The diagnoses were clinical amnionitis (four cases), possible neonatal sepsis (four cases), and neonatal sepsis (one case). One patient had more than one diagnosis. Of the eight patients with infection, delivery was accomplished in seven because of low biophysical score, four of whom developed intrapartum amnionitis, and in one because of spontaneous onset of labor. Of the remaining 65 patients with no infection, delivery was accomplished in 41 because of spontaneous onset of labor, in 14 because of low biophysical score (7 or less), in seven because of moderate to severe variable decelerations on electronic fetal heart rate monitoring, and in three because of suspected abruptio placentae. There was one false negative biophysical profile assessment in a fetus born vaginally who went on to develop possible neonatal sepsis. There was one neonatal death (1.3%) in the population studied; this fetus was 26 weeks' gestation and was delivered by cesarean section because of a low biophysical score. The infant died of disseminated sepsis and prematurity.

Comment

The fetal biophysical profile has been described recently as an early predictor of fetal infection in patients with premature rupture of the membranes.[1] In that report, which involved the use of frequent fetal biophysical profile determinations, the individual biophysical variables—nonstress test, fetal breathing movements, fetal movements, and fetal tone—were found to be important in predicting infection outcome in the above sequence; however, the best predictor of outcome of infection was found to be the overall biophysical score. The first manifestations of fetal infection were nonreactive nonstress testing and loss of fetal breathing. The loss of fetal movement and fetal tone were late signs of infection. That study was only observational and the results of the fetal biophysical assessment were not used for management. These patients formed the control group of the present study. Based on the results of that study the authors formulated a protocol for following patients with premature rupture of the membranes based on daily fetal biophysical profile determinations.

The purpose of the present study was to evaluate the efficacy of this protocol using daily fetal biophysical assessment in the management of patients with premature rupture of membranes and to see if such an approach would improve the outcome of pregnancy in these patients. The outcome of pregnancy of the study group was also compared with another historic group (amniocentesis group) managed by a protocol of transabdominal amniocentesis on admission to the hospital; the results of such a protocol have been reported previously by our group.[2] All three groups were similar in terms of risk factors for development of infection (Table I).

The present data suggest that management of premature rupture of the membranes with daily fetal biophysical assessment reduces the frequency of maternal and neonatal infection. The percentage of patients who developed infection in the study group (10.9%) was significantly less than in the control group (30.1%). This represents a reduction in our infection rate by almost two thirds. In the control group 18 patients had a low biophysical score and 16 (89%) developed infection. However, that study was observational and delivery was not undertaken in patients with low biophysical scores. In the majority of these 16 patients with infection (10 of 16), delivery occurred more than 2 days after the first abnormal fetal biophysical assessment. In the present study there were 21 fetuses with low biophysical scores; however, immediate action and prompt delivery was undertaken in all cases based on the abnormal biophysical assessment. This resulted in an overall infectious outcome (number of patients with infection) of 10.9%. The incidence of possible neonatal sepsis and neonatal sepsis were also lower in the study group compared with the control group (5.4% versus 13.6% and 1.3% versus 9.5%), but possibly because of the small numbers this did not reach statistical significance. However, when combined possible neonatal sepsis and neonatal sepsis were considered together, the overall neonatal infection was significantly lower in the study group (6.7% versus 23.2%). These data support the findings of our earliest studies[1,6] in which we have reported that the fetal biophysical profile is a good predictor of fetal infectious compromise. As to the significance of the higher 5-minute Apgar scores in the study group, one speculation is that it might be a reflection of the lower incidence of infection in the study population at the time of delivery. A higher incidence of low 5-minute Apgar scores given to infants born of mothers with clinical infection has been reported previously.[1,2]

Compared with the amniocentesis group the study group was found to have a significantly lower frequency of neonatal sepsis and overall neonatal infection. This is in agreement with our previously reported experience[2] with transabdominal amniocentesis, which has shown that this protocol decreases the incidence of clinical amnionitis but does not improve the outcome of neonatal infection. The outcome of neonatal infection was reduced by fetal biophysical assessment, a modality

that reflects fetal status rather than the presence of intrauterine bacteria.

A prospective, randomized study would be the ideal design to address the question of whether management of premature rupture of the membranes with daily fetal biophysical assessment improves the outcome of pregnancy. Although scientifically desirable, such a study was ethically unacceptable to all maternal-fetal medicine subspecialists and neonatologists at our institution. Therefore we used historic groups for comparison. We feel that the similarity between the historic and study groups permitted a meaningful clinical comparison because all three groups consisted of consecutive patients who were studied prospectively and managed in a similar manner other than the indications for delivery.

Our protocol for following patients with preterm premature rupture of the membranes takes into consideration the condition of the fetus before deciding on the optimal plan of management. Our data suggest that this approach improves the outcome of pregnancy by reducing the incidence of maternal and neonatal infection, although in the current study it did not improve the perinatal death rate.

The effects of maternal ambulation on the nonstress test

Lawrence D. Devoe, M.D., Martha Arthur, B.S.N., and Nancy Searle, B.A.

Augusta, Georgia

Using a recently developed noninvasive telemetry device (model 8240A, Hewlett-Packard Co., Palo Alto, California), we studied, under controlled conditions, the effects of maternal ambulation on the nonstress test patterns of 100 near-term high-risk pregnancies, randomly divided into two equal groups who underwent three alternating 30-minute periods of ambulation and bed rest, beginning either with ambulation (group 1) or bed rest (group 2). Fetal heart rate data were captured and analyzed by a programmed microcomputer for group mean 30-minute fetal heart rate baseline rates and variability and incidences and dimensions of fetal heart rate accelerations and decelerations. Both groups were similar for the maternal and perinatal data examined. The fetal heart rate parameters analyzed were similar within and between each group during each 30-minute testing segment. No episodes of sustained tachycardia or bradycardia were observed. Although 13 fetuses in each group exhibited variable or late decelerations, the incidence of decelerations was no different during periods of rest or ambulation. Maternal ambulation does not elicit abnormal fetal heart rate responses in most high-risk fetuses and may be an acceptable alternative to conventional nonstress test conditions. (Am J Obstet Gynecol 1987;157:240-4.)

Key words: Maternal ambulation, nonstress test, fetal heart rate

The nonstress test, an accepted method of fetal evaluation,[1] is usually performed with the patient resting in a semirecumbent or lateral position. Such maternal testing conditions generate legible fetal heart rate tracings but do not reflect the extrauterine environment that the fetus encounters during normal daily levels of maternal activity. Earlier studies of fetal heart rate re-

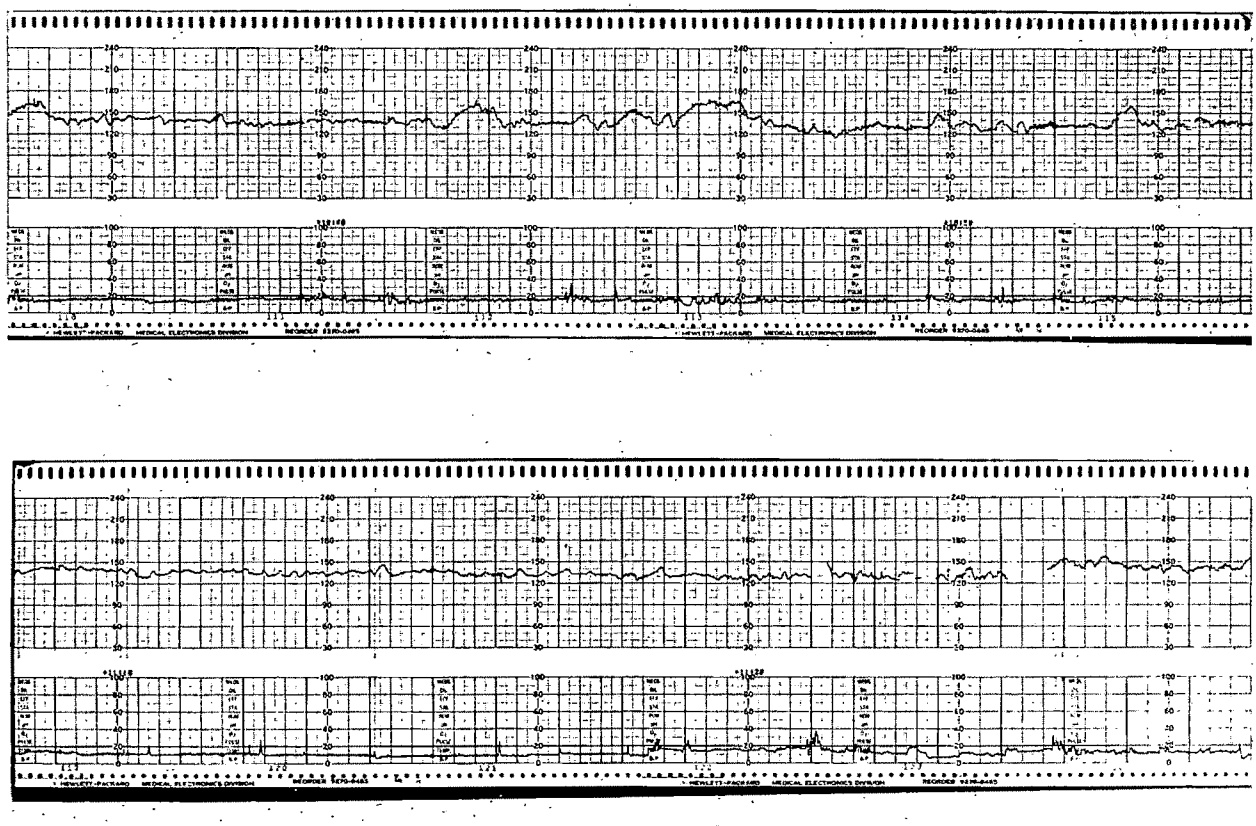

Fig. 1. *Upper panel* shows a fetal heart rate tracing obtained by telemetry during ambulation, and *lower panel* shows a fetal heart rate tracing obtained by telemetry during bed rest.

sponses to strenuous maternal activity[2-5] used relatively "noisy" fetal heart rate transducer systems, were performed on relatively small groups, or often contained discontinuous recordings of fetal heart rate patterns during the actual periods of maternal exercise. These studies did not consistently account for other testing conditions such as maternal fed state or time of day, and standard lengths of observation were not used. Subsequent investigations,[6-12] using more sophisticated systems to study fetal heart rate response to constant or graded levels of maternal exercise, have also not considered all of the above conditions associated with fetal heart rate testing. A variety of fetal heart rate responses have been observed during or after maternal exercise, including sustained tachycardia or bradycardia, with and without loss of baseline variability, as well as no change in baseline fetal heart rate. Newer noninvasive fetal heart rate telemetry units that produce high-quality Doppler fetal heart rate recordings have encouraged the present study of the effects of maternal ambulation on several fetal heart rate parameters obtained during nonstress testing (i.e., baseline fetal heart rate and its long-term variability and the frequency and dimensions of fetal heart rate accelerations and decelerations). In addition, we wished to determine whether maternal ambulation altered the time needed to achieve nonstress test reactivity and was a clinically practicable alternative to conventional testing conditions.

Material and methods

One hundred pregnant women were enrolled from the Obstetrical Clinic of the Medical College of Georgia. All met the following criteria: (1) gestational age established by menstrual data and ultrasonographic corroboration; (2) singleton fetus without anomalies; (3) established high-risk conditions for antepartum fetal testing; (4) intact amniotic membranes; and (5) no medical or physical limitations for ambulation.

Testing was performed under a standard maternal state protocol[13] that included test initiation between 8:30 AM and 1 PM, 2 hours postprandially, with the avoidance of smoking or other drugs that might affect the fetal cardiovascular or central nervous system. Fetal heart rate and tokodynamometric signals were transmitted to a model 8040A electronic monitor (Hewlett-Packard Co., Palo Alto, California) in the Doppler mode, by a noninvasive telemetry device (Hewlett-Packard model 8240A). These data were captured online by an IBM microcomputer, interfaced with the electronic monitor, which used a software program

developed and validated at the Medical College of Georgia.

Each study session lasted 90 minutes. Before testing the patients were randomly assigned to one of two groups of equal size. Patient in group 1 began their nonstress tests during ambulation for 30 minutes, followed by 30 minutes of bed rest and an additional 30 minutes of ambulation. For the nonstress tests of patients in group 2 the order of ambulatory and resting sessions was reversed. After a 60-second baseline recording of resting maternal heart rate, the patients walked in the fetal testing unit at a pace deemed similar to their normal pace at home. At the end of each ambulation period, maternal heart rate was remeasured. Ambulation took place at distances of 10 to 50 feet from the telemetry receiving unit. No study was discontinued for either fetal or maternal indications. Fig. 1 illustrates a typical fetal heart rate tracing obtained during ambulation *(upper panel)* and during bed rest *(lower panel)* in a patient monitored with the telemetry device.

Computer analysis generated 30-minute segments of mean baseline fetal heart rate, mean heart rate variation (coefficient of variation of mean beat-to-beat differences averaged each minute), signal loss, mean frequency, amplitude and duration of fetal heart rate accelerations exceeding 10 and 15 bpm, and the frequency and dimensions of fetal heart rate decelerations if present. Statistical comparisons of these fetal heart rate parameters were made for mean 30-minute testing sessions within and between each group. Other data analyzed included maternal age and parity, gestational age at delivery, test-to-delivery interval, birth weight, Apgar score at 5 minutes, method of delivery, and the presence of intrapartum or neonatal complications. Statistical methods included multiple *t* tests, analysis of variance, or χ^2 tests where appropriate.

Results

Maternal and perinatal outcomes. Both study groups were similar for the specific high-risk test indications as shown in Table I. Table II demonstrates that both groups were also similar for maternal gravidity and parity, gestational age at testing, test-to-delivery interval, birth weight, cesarean section rates for intrapartum fetal distress, and 5-minute Apgar scores. The actual incidences of intrauterine growth retardation, defined as birth weight below the tenth percentile for gestational age, and postmaturity syndrome were also similar for both groups (Table II). There was one neonatal death in group 2 of a 2497 gm male infant, born at 33 weeks' gestational age to a mother with class D diabetes mellitus. Death was attributed to the sequelae of profound intrapartum asphyxia, resulting from abruptio placentae.

Fetal and maternal heart rate parameters during ambulatory and nonambulatory testing sessions. Within each group, mean maternal pulse rate after ambulation rose by an average of 20.5 ± 4.5 (SD) bpm over mean resting pulse rates and did not differ significantly for any ambulatory session. Mean 30-minute baseline rate or variation and the incidence or dimensions of 10 or 15 bpm accelerations did not differ significantly from one testing session to another within or between the two groups (Table III). The incidence of fetuses with significant variable or late decelerations ranged from 12% to 18% during any 30-minute session and was most frequently associated with postmaturity syndrome (seven cases). Thirteen fetuses in each group exhibited occasional late or variable decelerations during one or more of their 30-minute test segments. The outcomes of these fetuses and their distribution during the testing segments are shown in Table IV. The actual frequency of variable or nonrepetitive late decelerations did not differ during any test period within or between the groups. Neither prolonged tachycardia nor bradycardia was observed during any of the testing sessions. Mean signal loss was significantly higher during maternal ambulation (7.7% ± 6.7% [SD]) than during bed rest (4.8% ± 6.8% [SD]) but did not exceed 22% in any single 30-minute period. The mean time required to achieve nonstress test reactivity (the presence of at least three accelerations exceeding 15 bpm and 15 seconds' duration) was similar whether testing was begun with ambulation (23.8 ± 20.5 minutes) or bed rest (19.7 ± 17.3 minutes). Only one nonstress test in each group failed to become reactive within 90 minutes; in each instance the pregnancy was complicated by intrauterine growth retardation.

Comment

Recent studies[6-12] indicate a renewal of interest in the acute effects of maternal exercise on the fetal cardiovascular system. Most have investigated activity levels more strenuous than those associated with ambulation. Few have maintained continuous fetal heart rate monitoring during the actual period of exercise,[12] and most

have confined their observations to preexercise and postexercise effects on fetal heart rate baseline in normal pregnant patients. With few exceptions,[10, 11] factors associated with fetal heart rate testing conditions, such as maternal fed state or time of day, were not specific in these studies. Although the impact of maternal dietary state on fetal activity may be controversial, data reported by Richardson et al.[14] and our group[15] suggest that quantitative differences in fetal biophysical activity patterns may exist when maternal fasting and fed states are compared. Finally, only one previous study has addressed the effects of maternal exercise on fetal heart rate reactivity.[16] This study examined only seven normal subjects, did not use continuous monitoring, and had observation intervals of 60 minutes or less. Therefore it is quite difficult to make valid direct comparisons

of these previous data with those of the present study.

The general impression suggested by earlier work is that the response of fetal heart rate baseline to maternal exercise, whether mild or moderate, may be quite variable in normal subjects and includes significantly elevated or reduced baseline fetal heart rates, as well as the absence of fetal heart rate baseline changes. The application of ambulatory fetal heart rate monitoring to the detection of fetal compromise in complicated pregnancies has been very limited, involving primarily the observation of changes in baseline fetal heart rate relative to the period of maternal exertion. Although Stembera[2] and Pomerance et al.[4] noted a positive correlation between alteration in baseline fetal heart rate and subsequent fetal outcome, neither report led to widespread clinical use of maternal exercise testing.

The present study differs from previous reports in that all subjects were drawn from a high-risk population. Fetal heart rate monitoring was continuous throughout the observation period, and fetal heart rate parameters were analyzed in addition to baseline rate. It does share a problem common to many of the earlier studies because maternal physiologic parameters other than heart rate were not measured and the rate of ambulation was not rigidly controlled. Therefore it is possible that in spite of similar postambulatory increases in maternal heart rate, the absolute level of exertion was not the same for all ambulatory patients. Our data suggest that maternal ambulation does not significantly alter the fetal heart rate patterns of either normal or compromised fetuses, when compared with those obtained during bed rest. Maternal ambulation is associated with higher loss of fetal heart rate signal and does not shorten the time required to produce a reactive nonstress test result. However, in no instances was fetal heart rate legibility unsatisfactory for visual interpretation. Telemetry devices that can transmit a high-quality signal may allow fetal heart rate testing to be performed in a setting more acceptable to patients who prefer not to be physically confined to a bed or chair. With the future development of sophisticated remote communication systems, this may also provide the potential for performing such testing at home, thus making ambulatory fetal heart rate testing even more convenient for high-risk patients. Whether the cost of this equipment and the inherent trade-off of increased signal loss could make this application more widely applicable requires further investigation.

Fetal monitoring during emergency obstetric transport

John P. Elliott, M.D., and Rebecca Trujillo, R.N.
Phoenix, Arizona

The practicality of fetal heart rate monitoring during fixed-wing transport of obstetric emergencies was evaluated. Fifty-seven transports were performed and 40 (70%) were monitored successfully with the electronic fetal heart rate monitor. External fetal heart rate monitoring was technically accomplished in 83% of monitored transports. Of the 40 patients monitored, 33 (83%) of the fetal heart rate tracings were considered useful for adequate evaluation of the fetal heart rate and contraction frequency. No patients had late decelerations during transport. At cabin pressures from 1100 feet to 7000 feet, fetal hypoxia as measured by late decelerations was not present in any patient. (Am J Obstet Gynecol 1987:157:245-7.)

Key words: Fetal heart rate, maternal transport, monitoring, fetal distress

Maternal transport of high-risk perinatal patients has resulted in improved survival, decreased short- and long-term morbidity, and decreased cost of hospitalization for the infants transported in utero and delivered at a tertiary care center.[1, 2] Short-distance transports can be accomplished by ambulance or helicopter, but longer-distance transports are usually accomplished with fixed-wing aircraft. The safety of travel for the fetus at altitude has not been adequately established as evidenced by different policies regarding flying while pregnant for transport nurses, flight attendants, and pilots.

Adequate assessment of the fetus in a high-risk situation would ideally use the technique that gives the most accurate information. Electronic fetal heart rate monitoring has become the accepted standard of care for intrapartum monitoring of high-risk pregnancies. Many of the transported patients are in labor and in a high-risk status for one or more reasons. Thus, electronic fetal heart rate monitoring during transport would be beneficial if it can be accomplished despite the adverse conditions of turbulent flight and patient positioning. Monitoring of the fetus during transport is currently accomplished most frequently by intermittent Doppler auscultation. A prospective study was designed to examine the usefulness of electronic fetal heart rate monitoring during fixed-wing transport of obstetric emergencies. A second problem addressed by this study is the effect of altitude on fetal oxygenation.

Material and methods

All patients included in this study were transported by Air Evac Air Transport Service operated by SamCor based in Phoenix, Arizona. The study population includes all fixed-wing maternal transports from October 13, 1985, to December 31, 1985. Three types of aircraft were used to transport patients: a twin-engine Cessna 414, a twin prop-jet 441 Conquest, and a twin prop-jet Gulfstream Turbo Commander 900. These aircraft were all pressurized and have been specially equipped for transporting pregnant patients. A Litton fetal heart rate monitor, model 550A (Litton Datamedix, Sharon, Massachusetts), was used during these transports, with an external Doppler ultrasonographic device for recording fetal heart tones and a tokodynamometer to detect uterine contractions. Five full-time and two part-time perinatal transport nurses accompanied all flights. All transport nurses have several years of obstetric experience in maternal-fetal intensive care. These nurses operated with protocol orders for medications and under the supervision of perinatologists in Phoenix. All patients were transported in left lateral position. The external monitors were applied and an attempt was made to monitor each transport. Twins were monitored intermittently because of the availability of only one Doppler recorder.

Monitor strips were evaluated by the authors with regard to quality of the tracing and the presence or absence of periodic fetal heart rate changes (accelerations, variable decelerations, and late decelerations). Maternal vital signs were monitored every 15 minutes during transport. Cruising altitude of the plane and cabin altitude were recorded.

Results

Fifty-seven emergency obstetric transports were performed by fixed-wing aircraft during the study period.

Table I. Indications for transport to level III tertiary hospital

Indication for transport	*Patients (No.)*
PROM or premature labor (<30 wk)	11

PROM, Premature rupture of membranes; CPD, cephalopelvic disproportion.

Patients were transported from rural areas of Arizona, California, and New Mexico to one of three tertiary-level maternity hospitals in Phoenix. One-way mileage between Phoenix and these communities ranged from 184 to 598 statute miles. Air travel time ranged from 25 minutes to 80 minutes. Cruising altitude ranged from 9500 feet to 23,000 feet and cabin altitude maintained by pressurization was 1100 feet to 7000 feet. Of the 57 patients transported, 40 (70%) were monitored successfully with the electronic fetal heart rate monitor from a technical viewpoint. Seventeen patients (30%) were not monitored. Reasons for failure to monitor included: maternal obesity (three patients), no monitor available (four patients), no inverter (a device that allows a 120 v appliance to be operated from an airplane battery) available (five patients), and other (five patients). If a monitor was available and working, 40/48 (83%) of the patients were monitored successfully. The remaining 17 patients were monitored with an intermittent Doppler device. The indications for transport are summarized in Table I.

The 40 fetal monitor tracings were evaluated with respect to the quality of the data on the tracing concerning fetal heart rate and uterine contractions. Of the 40 strips available for review, 33 (83%) were considered "good" quality. "Good" quality was defined as a clear, readable tracing at least 50% of the time enroute. It was considered useful for evaluation of fetal heart rate and contraction frequency. Seven (17%) were rated as "poor" quality. "Poor" quality was defined as an unreadable tracing >50% of the time on the monitor. Accelerations of the fetal heart rate (>15 bpm) were recorded on 36 tracings. Contractions were present on 29 tracings. Three patients had mild variable decelerations during flight. Two of these patients had premature rupture of membranes and preterm labor and one patient had premature labor with intact membranes. There was no evidence of late decelerations on any of the tracings.

Comment

Regionalization of perinatal health care has been developing since the mid 1970s. Neonatal intensive care units developed at large urban hospitals evolved into high-risk centers where patients with obstetric and neonatal complications could be sent to use the centralized availability of specialists in high-risk obstetrics, newborn intensive care, ultrasonography, pulmonary medicine, anesthesia, cardiology, etc. Neonates whose mothers were transported ante partum to the tertiary center were compared with those transported after birth in several studies.[3-5] Conclusions supported by these data include increased survival, decreased short- and long-term morbidity, and decreased cost of hospitalization for the infants transported in utero and delivered at the tertiary center. The benefits of maternal transport with delivery of the infant at the tertiary center resulted in lower perinatal mortality and morbidity rates in other studies.[6-8]

Transportation of the high-risk pregnant patient has been accomplished by ambulance, helicopter,[8] and fixed-wing aircraft.[7] In sparsely populated regions, long transport distances may be necessary. To ensure safety, both mother and fetus must be monitored closely. Reasons for maternal transports frequently involve premature labor, and tocolytic drugs are often used to inhibit labor while moving the patient. Women with hypertension or significant vaginal bleeding may be at risk for fetal distress. The added potential hypoxia of transporting these patients at altitude in a fixed-wing aircraft must be evaluated.

In this study we were able to successfully monitor 70% of our patients on fixed-wing flights by electronic fetal heart rate monitoring. During nine transports a monitor was not available so, if these are eliminated, 83% of transported fetuses were monitored successfully. The remaining 17 patients were monitored by Doptone. Eighty-three percent (83%) of these tracings were judged to be adequate to evaluate uterine activity and fetal heart rate data. Only three patients demonstrated decelerations (all mild variables) and 36 out of 40 had accelerations (considered a reassuring sign of fetal well-being). Even the "poor" quality tracings were useful in that each of these had at least a 10-minute strip that often contained acceleration of fetal heart rate. Certain factors were considered important and affected the quality of the tracings: excessive fetal movement preventing adequate tracing, turbulence affecting the airplane and the monitor, maternal obesity, and improperly applied monitors (belts too loose or too tight). It was felt that the monitor was useful in ob-

taining adequate tracings of fetal heart rate during transport. These data could then be used for therapeutic interventions: administering oxygen, tocolytic drugs, change of maternal position, etc.

The effect of altitude on fetal oxygenation has been a question since transport by plane began. We attempted to evaluate this question clinically by observing the fetal heart rate tracings for signs of hypoxia. Murata et al.,[9] reported data from monkeys that suggests that as the fetus becomes more hypoxic and then acidotic, the first signs of hypoxia observed in the fetal heart rate are intermittent late decelerations followed by consistent late decelerations and finally a loss of acceleration that progressed to death as the Po_2 was lowered and acidosis became worse.

Although a crude observation, there were no late decelerations noted on any tracing in this study. This represents indirect evidence that fetal hypoxia did not occur during these flights. None of the patients had fetal distress at the referring hospital before transport. The use of pressurized cabins seems to have little or no effect on fetal oxygenation as measured clinically by fetal heart rate monitoring. This question would also concern pregnant flight nurses, airline attendants, or pilots. It appears that a flight with cabin pressures between 1100 feet and 7000 feet is safe for the fetus at least for short periods of flight up to 80 minutes.

In summary, the benefits of electronic fetal heart rate monitoring can be used during the relatively long time of fixed-wing transport to monitor the fetus more accurately than with intermittent Doptone. Sixty-six percent of all of the transported patients could be monitored adequately; however, there were some patients who could not be monitored for various reasons. These patients would be followed frequently with Doptone fetal heart rate. Electronic fetal heart rate monitoring can be a valuable tool during fixed-wing transport of the obstetric emergency patient and her fetus.

We thank the transport nurses who helped compile the data: Phyllis Borges, R.N., Denice Jarles, R.N., Pat Kroldart, R.N., Mary-Ellen Nelson, R.N., Dale Resnick, R.N., Susan Robertson, R.N., and Chris Rogers, R.N.

We dedicate this article to Pat Kroldart, R.N., who died during a transport in 1987.

Congenital heart block and cardiac anomalies in the absence of maternal connective tissue disease

Lewis Shenker, M.D., Kathryn L. Reed, M.D., Caroline F. Anderson, R.D.M.S., Gerald R. Marx, M.D. Richard E. Sobonya, M.D., and Anna R. Graham, M.D.

Tucson, Arizona

The association of congenital heart block with maternal connective tissue disease and autoimmunity has been recently reported. Two cases of heart block were diagnosed in utero at 23 and 24 weeks' gestation. Both mothers had extensive workups for connective tissue disease that were negative. Two-dimensional and Doppler echocardiograpy were performed in utero and both infants had left atrial isomerism, atrioventricular canal defects, and severe hydrops in addition to heart block. Review of the recent literature identifies a subset of congenital heart block in which the mothers have no evidence for connective tissue disease, and the fetus or neonate has complex cardiac malformations and hydrops. The common features in these babies are atrioventricular canal defects and isomerism. No reports of congenital heart disease among the children of mothers with connective tissue disease fit this description. Our recent experience and literature review emphasize the previously known association between congenital heart block and congenital heart disease. This association is especially important in light of the poor prognosis for this group of fetuses and neonates. (Am J Obstet Gynecol 1987;157:248-53.)

Key words: Congenital heart block, atrioventricular canal defect, isomerism, polysplenia, asplenia, connective tissue disease

Congenital heart block can now be diagnosed prenatally[1] and its association with maternal connective tissue disease has been reported.[2, 3] We diagnosed congenital heart block in two fetuses whose mothers did not have clinical or laboratory evidence of connective tissue disease. Both fetuses had severe heart disease and hydrops. We reviewed the literature to determine whether this association was common. We found an association of congenital heart block with specific cardiac anomalies in the absence of maternal antibodies. Perinatal outcome in these cases was almost uniformly fatal.

Case reports

Case 1. Z. B., an 18-year-old black woman, gravida 2, para 1, had a fetal heart rate of 60 bpm reported at 23 weeks' gestation. The initial fetal cardiac ultrasound study, with two-dimensional, M-mode, and Doppler echocardiography, confirmed the diagnosis of complete heart block with an atrial rate of 80 bpm and a ventricular rate of 45 bpm (Fig. 1.) No ascites or pericardial and pleural effusions were present. Maternal anti-SSA, anti-SSB, and antinuclear antibodies were negative.

An ultrasound study at 26 weeks' gestation revealed persistent heart block with bilateral ventricular hypertrophy. The atria were dilated and no atrial septum could be identified. A common atrioventricular canal with a common atrium, single atrioventricular valve, and ventricular septal defect was diagnosed (Fig. 2). A small pericardial effusion was noted.

Ultrasound examinations were repeated at 1- to 2-week intervals. The outflow tracts appeared abnormal with a hypoplastic-appearing pulmonary artery and a dilated ascending aorta.

Genetic amniocentesis was performed; the karyotype was reported as 46,XX inv (4) (p14q21). Polyhydramnios and massive fetal edema with pleural effusions developed while the fetus was under observation. At 33 weeks' gestation, fetal movement had ceased and ultrasound examination confirmed the diagnosis of fetal death. Labor was induced and the patient was delivered of a stillborn breech infant weighing 1780 gm.

Postmortem examination revealed polysplenia with bilaterally left-sided bilobed lungs and left atrial iso-

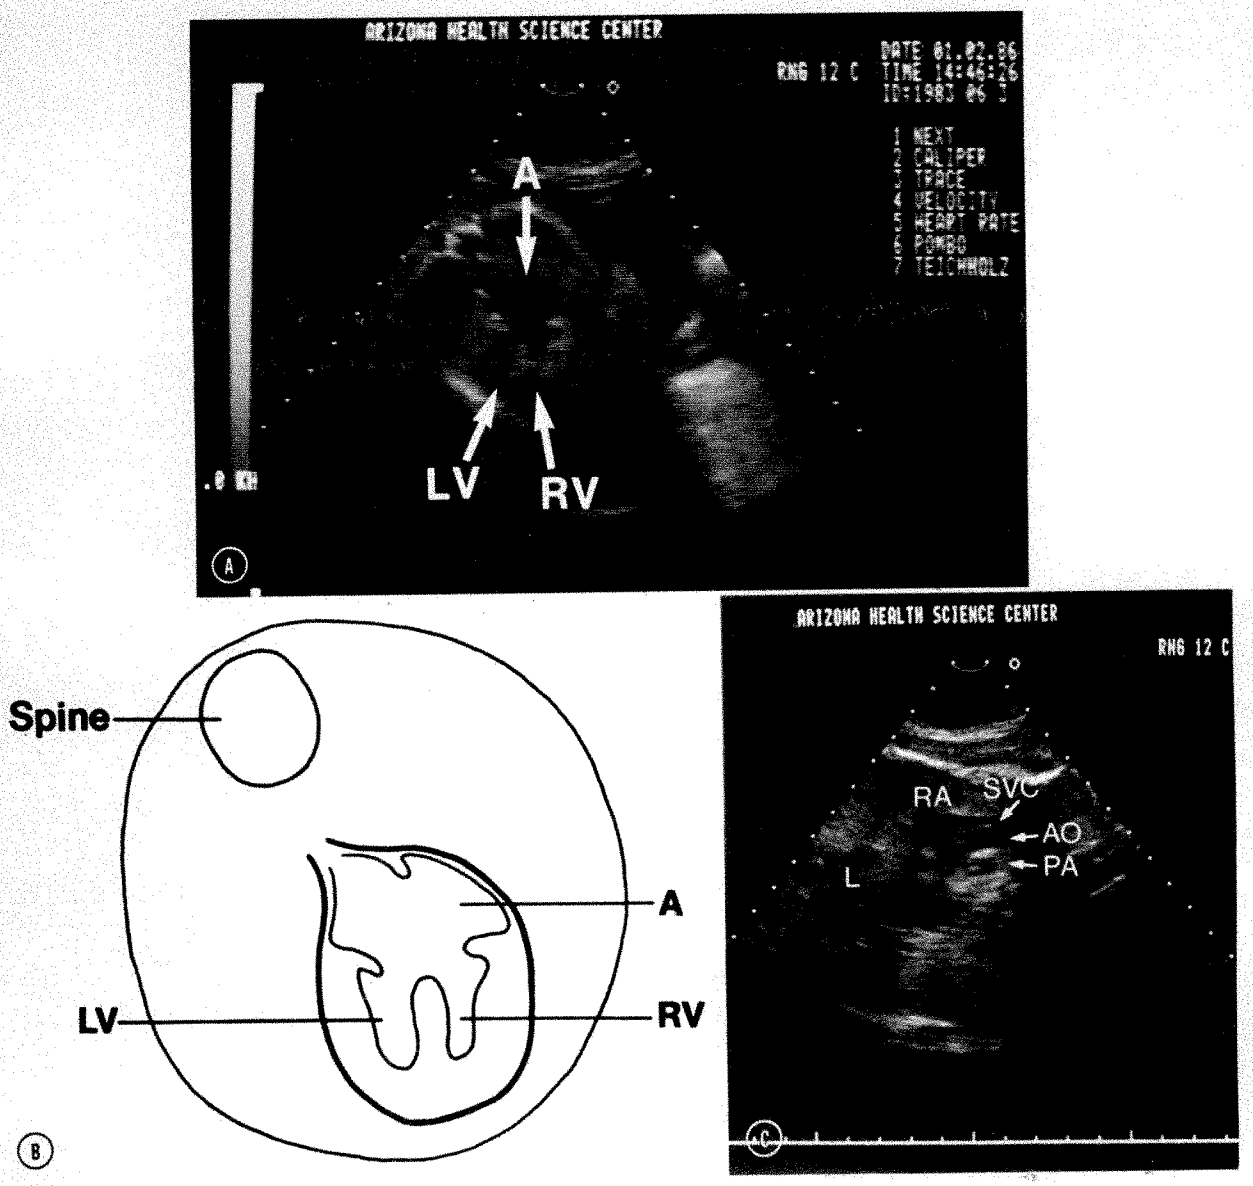

Fig. 3. Two-dimensional studies in Case 2. **A,** Two-dimensional ultrasound study. **B,** Line drawing. *A:* Atrium; *RV:* right ventricle; *LV:* left ventricle. **C,** Right side of atrium *(RA)* is seen with superior vena cava *(SVC)* entering; no inferior vena cava is seen. *AO:* Aorta; *PA:* pulmonary artery; *L:* liver.

merism. The suprarenal portion of the inferior vena cava was interrupted with azygous venous continuation into the superior vena cava. Bilateral superior venae cavae were identified. A common atrium, complete atrioventricular canal, and severe right ventricular outflow tract obstruction were present. Malalignment and inferior displacement of the parietal band with severe infundibular pulmonic stenosis and probable pulmonary atresia were found with a very hypoplastic main pulmonary artery. The aorta was dilated and overrode the interventricular septum. Cardiomegaly, pleural effusions (20 ml on each side), and pericardial effusion (5 ml) were confirmed.

Case 2. M. M., a 36-year-old woman, gravida 4, para 1, abortions 2, was referred at 22 to 23 weeks' gestation for fetal cardiac studies with a persistent fetal bradycardia (90 bpm). Anti-SSA, anti-SSB, and antinuclear antibodies were absent. Her first pregnancy was uncomplicated; her second pregnancy was terminated with the diagnosis of trisomy 21 at 16 weeks' gestation. Her third pregnancy resulted in a first-trimester spontaneous abortion. During the current pregnancy, chorionic villus sampling was performed at 8 weeks; the karyotype was 46, XX.

On fetal cardiac examination ventricular hypertrophy and an atrioventricular septal defect were diag-

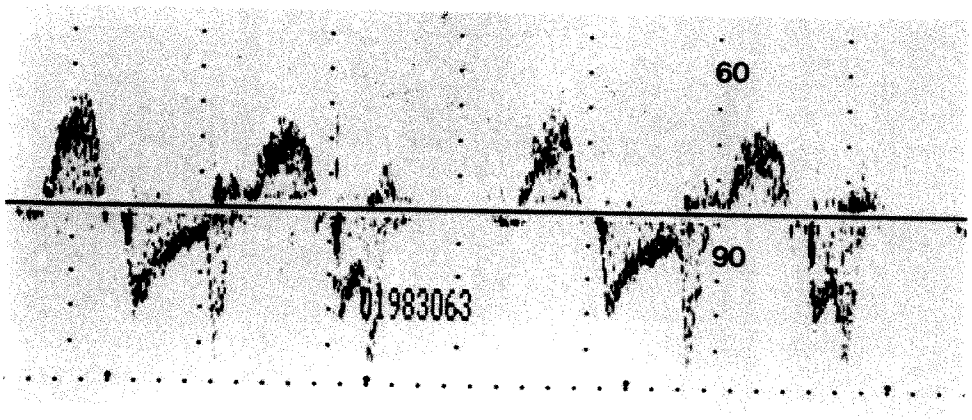

Fig. 4. Doppler echocardiogram of left ventricular inflow and outflow in Case 2. Ventricular (aortic outflow, above zero line) rate is 60 bpm; atrial (second peak of mitral inflow tracing, below zero line) rate is 90 bpm (3:2 block).

nosed (Fig. 3, *A* and *B*). The inferior vena cava was not identified (Fig. 3, *C*). Pleural effusions were present. On M-mode echocardiography, the atrial rate varied between 90 and 100 bpm; the ventricular rate was between 60 and 75 bpm. The rhythm was suggestive of a second-degree Mobitz type II block (Fig. 4).

By 32 weeks of pregnancy, polyhydramnios and fetal ascites had appeared. Cesarean section was performed at 33 weeks at the request of the parents, both of whom were physicians. The hydropic infant weighing 2600 gm had an Apgar score of 1 at 1 minute and 5 minutes. Despite initial attempts at resuscitation, ventilation of the lungs was unsuccessful and the infant died.

Postmortem examination revealed polysplenia, bilateral left-sidedness, and left atrial isomerism with an atrioventricular septal defect, bilateral superior venae cavae, and myocardial hypertrophy (Fig. 5). There was significant left ventricular outflow tract obstruction; the aortic anulus was narrowed, with a trileaflet aortic valve and poststenotic aortic dilation. A central liver, absence of the gallbladder, chronic stenosing cholangitis, and malrotation of the bowel were found. Ascitic fluid volume was 385 ml.

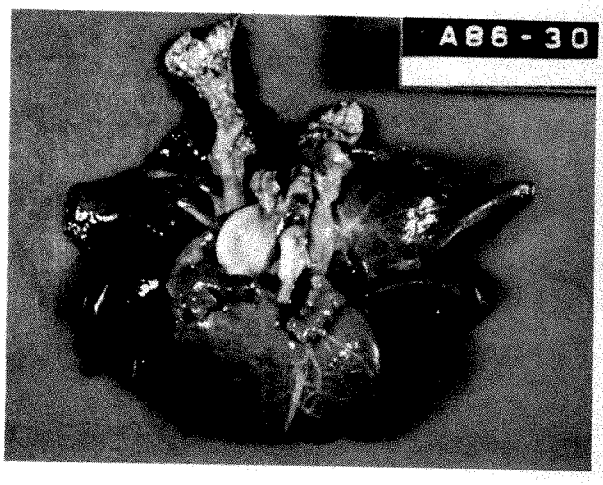

Fig. 5. Heart and lungs from Case 2. Cardiac enlargement, bilobed lungs, left atrial isomerism, and bilateral superior venae cavae are present. Note the disparity between the sizes of the great arteries.

Comment

Our findings in these two patients with congenital heart block without maternal connective tissue disease led us to a literature search to discover similar associations. Congenital heart block occurs in 1/20,000 neonates.[4] In many instances, maternal serologic test results positive for a variety of antibodies related to connective tissue disease have been described.[5] There were 60 cases with sufficient data to document the association between connective tissue disease in mothers of some babies with congenital heart block. In those patients, congenital heart block is accompanied by cardiac malformations in 23%. Twelve children had endocardial fibroelastosis and 14 had congenital heart disease. Six had a patent ductus arteriosus; two had dysplastic pulmonary valves; five had L-transposition. No complex cardiac abnormalities with isomerism were found.[3]

Review of the recent literature on congenital heart block discloses a group of patients in whom the diagnosis of congenital heart block was made either prenatally or in the immediate neonatal period and in whom all fetuses had complex congenital heart disease, usually accompanied by fetal hydrops. Twenty-six cases of congenital heart block accompanied by congenital heart disease diagnosed in the antepartum or immediate neonatal period have been reported since 1979 (Table I). The mothers of these children had no clinical or laboratory evidence of connective tissue disease. In each of these cases, the cardiac anomalies of atrioventricular septal defects and isomerism were present. Case 6 met all the criteria for left isomerism, but

polysplenia was not described. Case 19 had only a "large ventricular septum defect" on postmortem examination. Twenty-one fetuses and neonates had ultrasound, cardiac catheterization studies, angiography, and/or autopsy findings diagnostic of left isomerism with polysplenia. Four cases (Cases 21 to 24) had right isomerism and asplenia.

Twenty percent of patients with structural heart disease and isomerism have heart block.[13] All fetuses or neonates with congenital heart block diagnosed prenatally or shortly after birth who had structural cardiac anomalies uniformly had predictable major and complex lesions of the heart as well as either left or right isomerism. To date, no reported mothers with laboratory or clinical evidence of connective tissue disease have been delivered of babies with isomerism. These facts are consistent with different pathologic mechanisms for the conduction abnormality and the structural abnormalities, depending on the presence or absence of abnormal maternal antibodies typical of connective tissue disease.

The pathologic basis for complete heart block in patients with left isomerism has been described by Ih et al.[11] There is duplication of the atrioventricular node; the separate nodes are connected by a sling of conduction tissue. In three patients with congenital heart block, an interruption of the connection of the sling to the ventricular bundles was seen. Garcia et al.[7] stated that the sling is an "anatomical substrate for the development of heart block" in patients with left isomerism. They described two patients who had normal sinus rhythm converting to heart block over a period of years.

The development of heart failure in utero manifested by fetal hydrops appears to be an inevitable com-

plication of the combination of atrial isomerism, complex cardiac malformations, and heart block. Hydrops was reported in almost every case with clinical information available. Only one surviving patient has been described. When the diagnosis was made prenatally or at birth, there were 17 neonatal deaths, three stillbirths, and three induced abortions.

The patients reviewed and reported on manifested the most severe expression of isomerism. When isomerism is accompanied by heart block, atrioventricular septal defects, and hydrops, the affected fetus is almost uniformly unsalvageable. Despite the advances in pacemaker therapy of congenital heart block uncomplicated by anatomic abnormalities, the very high perinatal mortality of the group of patients described is discouraging. Our experience and the literature review suggest that cesarean section for a fetal indication is not justifiable.

Once the diagnosis of heart block has been confirmed by appropriate ultrasound studies and other causes of slow fetal heart rates such as persistent nonconducted atrial premature beats have been ruled out, the fetal heart must be carefully examined. Special attention should be directed to determine whether an atrioventricular canal defect, inferior vena cava, and abnormal pulmonary artery or aorta are present. Maternal antibody studies, such as antinuclear antibodies, anti–deoxyribonucleic acid antibodies, anti-Ro (anti-SSA) antibodies, and anti-La (anti-SSB) antibodies should be done, and a history and physical examination of the mother, particularly for the presence of connective tissue disease, should be performed. In the presence of fetal cardiac anomalies, a genetic amniocentesis is recommended, especially with the increased association of Down syndrome with atrioventricular canal defect. If hydrops is not present, expectant management is appropriate, and vaginal delivery is safe. In the presence of hydrops with a normal karyotype and without major abnormalities, delivery by cesarean section when lung maturity has been confirmed, or sooner if fetal surveillance indicates deterioration in fetal condition, is desirable. The hydropic fetus without lethal cardiac anomalies should not be subjected to labor. If isomerism, atrioventricular septal defect, and hydrops are diagnosed, interruption of pregnancy or the avoidance of cesarean section for fetal indications is recommended. It is important to include the consultation of pediatric cardiologists and neonatologists to individualize intrauterine and neonatal management.

Factors affecting psychological adjustment to a fetal death

Melody A. Graham, M.A., Suzanne C. Thompson, Ph.D., Mary Estrada, R.N., and Margaret Lynn Yonekura, M.D.

Los Angeles, California

The loss of a child in utero can be a tragic experience. The purpose of the present study was to examine some patient characteristics that may predict which women are likely to have problems in adjusting to the loss and to examine the effectiveness of interventions by care providers in facilitating emotional recovery. Twenty-eight women who were no more than 4 weeks post partum from a fetal death were interviewed while waiting to see their physicians at the fetal demise clinic at Los Angeles County Women's Hospital. It was found that women were less depressed after the loss if they already had children, if they did not blame themselves for the death, and if they received a picture of the infant or were allowed to see the infant. Women benefited from sympathy from the medical personnel and being kept informed of problems as they developed. (AM J OBSTET GYNECOL 1987;157:254-7.)

Key words: Coping, fetal death, blame, psychological adjustment

The loss of a child in utero is similar to the death of any loved one and is often associated with significant long-term psychological consequences.[1, 2] Unfortunately, patients often must carry the burden of the death alone because medical personnel, friends, and family members may not realize the extent of attachment that a mother has for her unborn infant and thus they underestimate the grief and sorrow that she feels.[3]

Not a lot is known about what affects positive psychological adjustment to this type of loss. The purpose of the present study was to examine some patient characteristics that may predict which women are likely to have problems in adjusting to the loss and to examine the effectiveness of interventions by care providers in facilitating emotional recovery.

Previous research using a cognitive adaptation model of coping has found that individual responses to a traumatic event depend on the meaning of the loss to the person experiencing it.[4] The meaning of a fetal death is likely to be affected by three patient characteristics: how much the woman wanted the child, whether she has other children, and whom she blames for the loss. The assignment of blame can be particularly important because these judgments are associated with feelings of being treated unfairly, the perception that a similar event can be avoided in the future, and distressing ruminations about the event. We measured these three patient characteristics to see if they predicted how well the women were coping with the loss.

The effects of two interventions on the part of medical care providers were also examined: providing the mother with a picture of the infant or an opportunity to see the infant and informing the mother about the cause of death. The recent literature suggests that it is helpful for parents to see their dead infant (despite deformities), hold the infant, name it, and bury it.[5, 6] Some hospitals have begun to take pictures of the child and give death certificates and mementos of the child to the parents to help establish the child's identity. However, the effectiveness of these procedures has not been established in a controlled study. Therefore, one goal of this study was to see if mothers who received pictures of the child or saw the infant would find it easier to deal with the loss.

If was also expected that knowledge of the cause of the infant's death would facilitate the recovery process. Research on other types of losses has found that it is particularly difficult for people to deal with a misfortune when they do not understand why it happened to them.[4] Also, guilt is the most common postmiscarriage emotion.[7] Knowing the cause of death may help alleviate some of this guilt.

Finally, the study examined women's perceptions of the ways in which medical personnel were supportive and helpful to them in dealing with the loss and ways in which the medical personnel were not helpful. It was hoped that the women's observations would provide additional information about ways in which care providers could aid in the recovery process.

Material and method

Twenty-eight women who were no more than 4 weeks post partum from a fetal death or perinatal death were interviewed while waiting to see the physician at the fetal demise clinic at Los Angeles County Women's Hospital, University of Southern California

Medical Center. The fetal demise clinic was established to ensure more consistent antepartum and postpartum medical care for patients who have experienced a fetal death. This clinic allows women to receive postpartum checkups and antepartum care in a setting away from women who have had a successful pregnancy. The clinic was designed to not only give consistent medical care to these patients but also attend to the psychological and emotional needs of the patient. Physicians are directed to give special attention to the patient's emotional needs, and patients who are particularly disturbed by the incident are referred to a social worker. Patients are encouraged to see, touch, and hold their infants if they feel comfortable doing so. Pictures are also taken of the child and offered to the parents. However, because the hospital is often overcrowded, these procedures may not always be completed. Therefore not all families are offered a chance to hold their child, and pictures are not always taken. All patients are encouraged to have an autopsy performed. However, a large number of patients refuse to have this procedure completed. The goal of the clinic is to have a supportive facility in which patients can be treated. However, because of overcrowding and understaffing the clinic does not always meet these high standards.

The average age of the respondents was 30 years, ranging from 15 to 39 years (mode 21). Ninety-six percent of the sample were Hispanic and spoke little or no English. On average, the respondents had been in the United States for 7 years. The sample was also very religious, with 92% of the respondents reporting that they considered themselves religious (56% considered themselves very religious).

The 30-minute interview was conducted by a nurse employed by the hospital. This nurse did not normally work in the fetal demise clinic. At the end of the interview the depression subscale of the Symptom Check List (SCL-90) was administered to each patient as a measure of coping. The SCL-90 is a multidimensional self-report symptom inventory oriented toward the measurement of psychological symptomatic distress. Information was also collected from the patient's medical chart. Family members were not allowed in the room during the interviews to ensure that the patient felt free to answer all questions. Interviews were conducted in the respondent's native language and tape recorded. Pearson correlation coefficients (r) were used to analyze the data.

Results

The fetus was carried an average of 36 weeks and weighed an average of 2373 gm. More than half the sample had pregnancy complications such as breech births and diabetes. This was the first pregnancy for 32% of the women, 36% were taking medications during their pregnancy, and 19% had received no prenatal care.

As a measure of attachment, women were asked about their feelings about being pregnant. Fifty-four percent of the women reported being very happy about being pregnant, 12% were unhappy about being pregnant, and the rest (34%) felt somewhat happy. However, degree of happiness about being pregnant was not related to depression for this sample.

Family situation. Although only 42% of the sample were married, 58% lived with the father of the infant. Married respondents were significantly less depressed than those who were single ($r = 0.39$; $p < 0.05$). Fifty-seven percent of the women had children already and 27% had more than two children. The number of children the respondent already had was also significantly related to depression; the more children a respondent had, the less depressed she was ($r = -0.43$; $p < 0.05$).

Blame. The most common attribution of blame for the death of the child was to God. Thirty-one percent of the people who attributed the death to God reported feeling that way "all of the time." Those who attributed the death to God were also significantly less depressed ($r = -0.33$; $p < 0.05$). Blaming oneself for the death was more common than blaming another person, but still only one fourth of the respondents reported feeling that something they did caused the infant to die. However, those who blamed themselves were significantly more depressed ($r = 0.34$; $p < 0.05$). Those who did blame themselves had difficulty articulating why they felt responsible. One woman stated, "I don't remember doing anything, but I think that way (blame myself) anyway." Women who were taking medication during the pregnancy were more likely to blame themselves for the death ($r = 0.36$; $p < 0.05$).

Nineteen percent of the women blamed some member of the medical profession for their child's death. Blaming the medical personnel for the death did seem to cause feelings of being cheated by the death, but was not significantly related to depression. All of the women who blamed the medical personnel felt cheated by the death and also felt that the death could have been avoided (for example, "The clinic doctor was irresponsible, in the morning there was a heartbeat by evening there wasn't a heartbeat, they should have done something." "The clinic doctors were trainees and didn't know what they were doing, I felt like a guinea pig . . . they can't even take blood right." "The doctor at the clinic was not the right doctor to see women with first pregnancies, I was supposed to see someone else.").

As can be seen by these remarks, the blame is not always warranted or justified (for example, all physicians at the clinic mentioned do the same thing) but demonstrates the need to find someone who is responsible for the death. As stated before, other-blame was

associated with strong feelings of being cheated and the sense that the death was unfair.

A common theme in the women's remarks was that the death was not fair because they had been told everything was going to be all right (for example, "Up till the end my baby was fine, it is not fair." "When I was experiencing the labor pains everyone was saying everything was fine with my baby, *then* they told me the baby was not all right."). Thus it appears that being told everything is going to be "ok" when it is not leads to stronger feelings that the death was unfair.

Cause of death. The leading cause of death was cord accidents (30%); 12% died of fetal anomalies. The cause of death was unknown in 27% of the cases. Even though the cause of death was known in most cases, only 42% of the respondents reported knowing why the infant died. This may be because respondents were interviewed before seeing the physician. Contrary to prediction, knowing the cause of death did not have an effect on depression. However, those who did know the cause of death were more likely to rate the physician as being helpful ($r = 0.32$; $p < 0.05$).

Pictures. Forty percent of the respondents received pictures of the infant. Those who received pictures were significantly less depressed than those who did not ($r = 0.35$; $p < 0.05$). Eighty-four percent were allowed to hold or see the infant. These respondents were also significantly less depressed ($r = 0.38$; $p < 0.05$). Because the criteria for who receives a picture or who sees the infant are somewhat arbitrary, differences among the groups were checked. Those who received pictures or saw the infant did not differ significantly from those who did not receive pictures on marital status, number of children, age of infant, or weight of infant at birth. However, women who received pictures of the infant were less likely to have had complications in birth ($r = -0.36$; $p < 0.05$).

Seeing pictures of the infant was also significantly related to variables other than depression. Women who saw pictures were less likely to blame themselves for the death ($r = 0.39$; $p < 0.05$) and were less likely to blame another person ($r = 0.39$; $p < 0.05$). Thus it appears that receiving pictures does have the positive effect that has been suggested in the literature.

However, one explanation for the finding that those who received pictures were less depressed is that women who were more emotionally devastated by the loss refused to accept pictures of their infants if they were offered. No record was kept of refusals, but we did have a measure of whether each woman had wanted to receive a picture. No one who received a picture mentioned that she did not want to receive the picture, but some women who did not receive pictures stated that they did not want them. Presumably, some of these women may have refused pictures that were offered to them. However, women who did not want and did not receive pictures were less depressed than those who wanted but did not receive them, so it is unlikely that the higher depression scores of those who did not receive pictures can be attributed to women who were more upset refusing the pictures.

Helpful and unhelpful support. Forty-six percent of the respondents rated the medical personnel as helpful almost always or most of the time. The majority of these respondents reported that what they found helpful was that the physician and nurses gave them sympathy. When asked for specific examples of this, respondents reported things like, "The nurses stayed with me and talked to me" or "The doctor gave me sympathy and tried to console me." Thirty-five percent found the medical personnel unhelpful. However, none of these women reported anything in particular as unhelpful. This may be because the interviews were conducted in the hospital by a nurse, so respondents may have been unwilling to mention specific criticisms of the medical staff. However, what the women who were less satisfied did report was that their physicians were helpful in only very limited ways (for example, by only providing the name of a cemetery). They did not feel that they received any emotional support from the medical personnel.

Comment

This study found that women who lost a child in utero were less depressed if they already had children. Presumably, these women knew that they could deliver a healthy child, so the death was less likely to arouse a sense of failure or responsibility for failed reproductive performance. This suggests that women who lose their first child in utero may be particularly likely to benefit from information that a healthy delivery is still possible for them.

The way that women attributed blame for the death was also related to psychological adjustment. Those who blamed themselves for the loss were more depressed than those who did not. Previous research on coping with a loss had found that self-blame is adaptive if it engenders feelings of control and the perception that one can act to avoid a similar misfortune in the future.[8] Evidently, women who blamed themselves in this study did not see their role in the loss as something that they could change and therefore avoid in the future. Because self-blame for this type of loss does not appear to be adaptive, it might be useful, where appropriate, for physicians to reassure women that they are not responsible for the loss.

The third patient characteristic measured, attachment to the child or how much the woman wanted the child, was not related to depression. This is surprising because one would expect that women who were more

emotionally attached to the unborn child would be more devastated by the loss. There are two explanations for this finding. First, asking the mother how she felt about the pregnancy is not an adequate measure of attachment. Further research with other ways of assessing attachment could test this explanation. Second, perhaps by the late stages of a pregnancy almost all mothers are attached to the unborn child, regardless of whether the pregnancy was desired. Given that there is a high level of attachment by most mothers, other factors such as who is blamed for the death or whether the mother has other children are more predictive of differences in coping with the loss.

Contrary to what was expected, knowing the cause of death was not related to how depressed a woman was. It appears that understanding the cause of one's misfortune is not as important for this type of loss as it has been found to be for other negative experiences. However, this may be a culturally based finding. The participants in this study had been in the United States for an average of only 7 years. A different cultural group may find it more important to understand the cause of death.

Seeing the infant or receiving a picture of the infant appeared to be quite helpful for the respondents. This is a fairly easy intervention that can be implemented in hospitals and may make recovery from the loss easier. Not only did those who received pictures feel less depressed, they also did not blame themselves or another person as much. Seeing a picture or seeing the infant allows the parents to mourn a real child and makes the event more real.

The women's observations on helpful and unhelpful behaviors of medical personnel suggest two things. One, women in these circumstances seem to appreciate and benefit from shows of sympathy and understanding from medical care providers. Physicians who can provide emotional support during interactions with the patient may help the recovery process. Two, women find it especially stressful to lose a child shortly after they had been reassured that there were no problems. In some cases, when complications are not evident immediately, it may be impossible to avoid giving misleading information. However, it appears that whenever possible, women should be kept informed of problems that are developing.

One limitation of the study should be noted. The women's adjustment to the loss was examined 4 weeks post partum, a time that is relatively early in the grieving process. There was a wide range of depression scores suggesting that some women were coping better at this time than were others, and one would expect that those who were handling the grief well at this stage would continue to be the more effective copers. However, the suggestions drawn from this study are most applicable to those patients in the acute stages of grief.

The loss of a child in utero is a tragic experience for most women. This study points out a number of ways that medical care providers can ease the recovery process for women faced with such a loss.

Erb's palsy and fetal bruising after external cephalic version: Case report

Boris M. Petrikovsky, M.D., Hema N. DeSilva, M.D., and Fred D. Fumia, M.D.
Farmington and Hartford, Connecticut

An unusual fetal complication, Erb's palsy and fetal bruising, after successful external cephalic version is reported. Importance of fetal weight estimation prior to the attempts to perform a version is stressed. (AM J OBSTET GYNECOL 1987;157:258.)

Key words: External cephalic version, fetal trauma, Erb's palsy.

External cephalic version is known to be associated with obstetric (premature labor, bleeding, etc.) and fetal (fractured bones, spinal cord injuries, prolonged bradycardia requiring emergency cesarean section, umbilical cord prolapse, meconium aspiration) complications. Antepartum fetal death is a rare but grave accident. In a large series of Bradley-Watson,[1] five of the eight deaths occurred after successful version and three after a failed procedure. To our knowledge, however, no case of antenatal peripheral nerve injury has been reported. We present such a case.

Case report

A 33-year-old woman, para 1-0-1-1, was admitted at 41 weeks' gestation with breech presentation for an external cephalic version. The patient had an uncomplicated pregnancy. Ultrasound examination confirmed a term gestation and breech presentation. The placenta was located posteriorly. Version was successfully performed under sonographic guidance with the use of a tocolytic agent without difficulty. A nonstress test done after the version was reactive. Five hours after version, the patient went into labor and was delivered of a 4.11 kg infant by vacuum extraction. The vaccum extractor was applied when the head was directly OA at +3 station. The anterior left shoulder was delivered easily, and the infant cried spontaneously, receiving Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Physical examination at delivery revealed Erb's palsy on the left side as well as bruising of the left shoulder and adjacent areas of the anterior and posterior chest wall. Radiologic evaluation did not reveal clavicular or humeral fractures or subluxation of the left shoulder.

During the hospital stay the infant showed improvement in movement of the left upper extremity with some limitation of abduction at the shoulder. Progressive improvement has been seen on follow-up at 2 weeks. Only mild residual weakness from Erb's palsy was still present in the fourth week.

Comment

The presence of visible bruises at the time of delivery, in view of the easy delivery of the shoulder girdle, can be ascribed to external cephalic version. We think that fetal weight should be estimated prior to the procedure and version not undertaken in the case of a large fetus. The fact that external cephalic version is "easy" and successful does not guarantee its safety for the fetus. Immediate effects of external cephalic version on the fetus are unknown because of the prolonged period of time between the procedure and delivery. In Ellis' series[2] of 314 external cephalic versions only four infants were delivered within 7 days of the attempted procedure.

A reusable plastic training model for teaching Papanicolaou smear technique

Charles R. B. Beckmann, M.D., M.H.P.E., Daniel L. Clarke-Pearson, M.D., and Ray Evenhouse

Chicago, Illinois

A reusable plastic Papanicolaou smear training model was developed to teach the techniques of the Papanicolaou smear. The model design allows immediate feedback and opportunity for skills practice, yet it is efficient and cost effective. Its use is recommended for instruction in the techniques of the Papanicolaou smear. (Am J Obstet Gynecol 1987;157:259-60.)

Key words: Papanicolaou smear, medical education, training model

Some physicians avoid performing Papanicolaou smears as part of a pelvic examination because they are uncomfortable with the techniques. Others perform the examinations but because of poor technique produce a Papanicolaou smear that is inadequate for cytopathologic evaluation. It is reasonable to assume that the difficulties physicians experience are related in part to inadequate training. Training in the Papanicolaou smear technique usually accompanies instruction in the pelvic examination, which has improved greatly with the adoption by most medical schools of the gynecologic teaching associate model.[1] Performance of the Papanicolaou smear, however, is different from the remainder of the pelvic examinations in that it is strictly a psychomotor skill so that the benefits of the gynecologic teaching associate training system may not carry over to instruction in the Papanicolaou smear. Further, many educators and gynecologic teaching associates have reservations about gynecologic teaching associates having multiple Papanicolaou smears.

To provide improved instruction in the Papanicolaou smear technique while remaining within the gynecologic teaching associate teaching model, we developed a plastic reusable Papanicolaou smear training model. It is composed of three parts: a clear plastic square support base, a clear plastic tube to simulate the vagina,

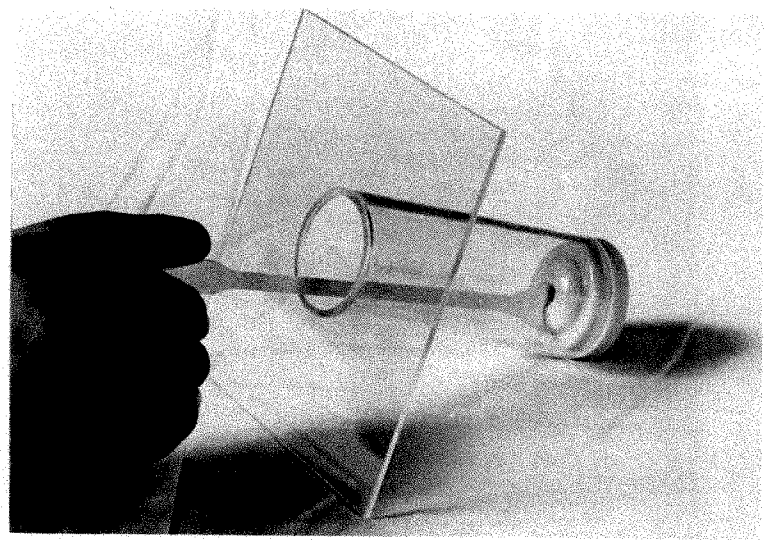

Fig. 1. The reusable plastic Papanicolaou smear training model.

and a molded, flesh-colored, soft rubber artificial cervix. The latter is molded after the endocervical end of a Papanicolaou smear spatula so as to facilitate practice. The parts are interchangeable between the training models, which may be disassembled for easy storage and cleaning. The design of the training model allows both the instructor and the student to observe the student's practice from the side-on vantage point and from an end-on vantage point (see Fig. 1). Of the two vantage points, the former is impossible in an actual patient but is of considerable value in guiding the student toward acceptable technique.

After viewing a videotape demonstrating the technique of the Papanicolaou smear with the plastic training model, students practice the techniques of the Papanicolaou smear, including correct maneuvers with spatula and cotton-tipped applicator, in obtaining the sample and applying it to a slide. Clear lubricant is applied to the end of the artificial cervix so that there is a "sample" to practice spreading on slides. Each student is allowed to practice the Papanicolaou smear technique under faculty supervision until his technique is satisfactory.

Use of the plastic Papanicolaou smear training model in this manner allows emphasis of the essential principles of the Papanicolaou smear technique: (1) proper sampling of the endocervix with cotton applicator, brush, or aspirator; (2) proper sampling of the exocervix with the wooden or plastic Papanicolaou smear spatula; (3) proper spreading of cytopathologic material on the glass slides in a manner that avoids clumping of the mucus on the slide; (4) rapid fixation of the slides to avoid air-drying artifact of the specimen. These essential principles may be emphasized by immediate feedback based on direct observation of the student's performance and by the opportunity for practice until the student has mastered the techniques. Such feedback and the opportunity to practice are key to successful skills instruction.[2]

The plastic Papanicolaou smear training model has been used for 1 year in the instruction of second- and third-year medical students and resident physicians. Both groups of learners, disparate in their experience, uniformly expressed the opinion that instruction on the technique of the Papanicolaou smear by use of the plastic training model was efficient and effective. Studies are now underway to ascertain if there is an improvement in the quality of Papanicolaou smears received. On the basis of our experience with this training model, we are confident in recommending it for instruction in the techniques of the Papanicolaou smear.

Multiple primary gynecologic neoplasms

Peter G. Rose, M.D., Edward E. Herterick, B.S., John G. Boutselis, M.D., Melvin Moeshberger, Ph.D., and Larry Sachs, Ph.D.
Columbus, Ohio

Some patients may be predisposed to the development of more than one gynecologic neoplasm. We evaluated 130 cases of synchronous or metachronous tumors among 5967 patients followed up by The Ohio State University Gynecologic Tumor Registry for the past 44 years from 1939 to 1983. Based on primary tumor site and invasive behavior, expected incidences for a specific second malignancy were calculated by the person-years method. A second malignancy of the lower genital tract occurred in patients with cervical, vulvar, and vaginal cancers, 1.6%, 4.3%, and 9.6%, respectively, which supports the theory of multicentric cancer of the lower genital tract. Prior radiation therapy was rarely associated with increased second gynecologic malignancies (two of 41 patients, 4.9%). Four patients had three gynecologic tumors. (AM J OBSTET GYNECOL 1987;157:261-7.)

Key words: Multiple cancers, gynecology, radiation therapy

Theodore Billroth[1] documented multiple primary cancers in 1889, and the literature now totals more than 30,000 patients with multiple malignancies. This volume of reports represents both an increased interest in such patients and improved patient survival extending years of neoplastic risk. Physicians fascinated and perturbed by patients with multiple malignancies have raised certain questions: (1) Is the patient cancer prone (i.e., is the incidence of a second malignancy greater in patients with cancer than in the general population)? (2) Is there a genetic, immunologic, or environmental factor responsible for multiple primary cancers? (3) Is the prognosis for the patient altered by multiple malignancies? (4) What alterations in management are needed?

Multiple malignancies of the female genital tract have been reported.[2-10] These reports have identified associated pelvic malignancies, and this information has been useful to physicians involved in gynecologic evaluation of patients with cancer and surveillance. Whether these associated malignancies occur by random event or at a statistically increased rate has not been widely studied.

At Ohio State University, a gynecologic tumor registry established in 1939 maintains records on 6489 patients. The first case of multiple malignancies of the genital tract was recorded in 1941. To determine if patients with a gynecologic tumor were at an increased risk of a second gynecologic tumor, we have analyzed 130 cases of multiple malignancies of the genital tract derived from our registry.

From the Departments of Obstetrics and Gynecology, Preventive Medicine, and Biostatistics, The Ohio State University.

Material and methods

One hundred fifty-six cases of multiple malignancies from the gynecologic tumor registry from 1939 through December 1983 were reviewed. Patients with pelvic malignancies of unknown primary site and cancer metastatic to the pelvis were excluded. In addition, to be included in this study, cases had to fulfill the criteria of multiple primary malignancies proposed by Warner and Gates[11] in 1932: (1) Each of the tumors must present a definite picture of malignancy. (2) Each must be distinct. (3) The probability that one is a metastatic lesion from the other must be excluded.

The evaluation of vaginal cancer after cervical cancer poses problems because of similar histologic findings and anatomic location. The following combinations were accepted: (1) cervical carcinoma in situ with subsequent vaginal carcinoma in situ, (2) cervical carcinoma in situ, with subsequent vaginal invasive cancer, (3) cervical invasive cancer with subsequent vaginal carcinoma in situ and (4) cervical invasive cancer with subsequent vaginal invasive cancer occurring more than 5 years after the patient displayed no evidence of disease.

Careful review of the operative and pathologic reports excluded 21 patients who failed to meet either the criteria of Warner and Gates or vaginal cancers after cervical cancer previously proposed. Five patients with histologically different cancers occurring at the same gynecologic site were also excluded. These patients were excluded because of the absence of histologically specific incidence data over the time period of this study. The 5967 registry patients had tumor types suitable for inclusion in this study. The remaining 130

cases were divided into synchronous or metachronous tumors. Synchronous tumors were defined as tumors that were either diagnosed concurrent with the primary tumor, discovered at the primary surgical procedure, or occurred within 1 year of the primary tumor diagnosis. A malignant site was designated the primary cancer if it initiated the patient's evaluation or surgical procedure or was chronologically diagnosed first. Metachronous tumors were simply defined as tumors diagnosed greater than 1 year after the primary neoplasm.

To determine whether the second malignancy was statistically associated with the primary malignancy, expected incidence rates for a second malignancy were calculated according to the person-years method[12] for subgroups of patients with the same tumor site and type (invasive versus noninvasive). Incidence rate tables for invasive and noninvasive gynecologic malignancies occurring between 1939 and 1983 were obtained from the Connecticut tumor registry.[13] For synchronous tumors, the cumulative expected incidence rate was calculated by totaling each patient's expected rate at the year of tumor diagnosis. For metachronous tumors, cumulative expected incidence rates were calculated by totaling each patient's expected rate at the year of diagnosis and for each subsequent year the patient was followed. These values were termed standard incidence rates. Patients with multiple malignancies were included in the incidence calculations based on their primary tumor. For this subgroup of patients, follow-up was calculated until the date of diagnosis of a second malignancy. The statistical significance of the calculated ratio, observed to expected second malignancies, was tested with a table of significant factors for the ratio of a poisson variable to its expectation.[14] To determine if prior radiation therapy was a contributing factor to subsequent malignancy, the ratios of standard incidence rates were calculated as described by Gail[15] for subgroups of patients with or without prior radiation therapy for each tumor combination.

Results

Synchronous pelvic malignancies. Forty-five patients had synchronous cancers. Twenty-one patients (47%) had multiple cancers confined to the lower genital tract; 10 (48%) of these patients were initially evaluated for cervical lesions, seven (33%) for vulvar lesions, and four (19%) for vaginal lesions. In situ lesions accounted for at least one malignancy in 66% of these 21 patients. Eleven patients had concurrent uterine and lower genital tract malignancies, 91% of which were cervical neoplasms. In all cases, the cervical and uterine histologic findings were distinct. Of the 15 ovarian tumors, eight were associated with uterine cancer; of these only one was an endometrioid ovarian tumor and one a stromal ovarian tumor, an androblastoma (Table I).

There were three cases of triple malignancies of the

CIS = Carcinoma in situ; Cx = cervix; NOS = not otherwise specified.
*All lesions are invasive unless specified carcinoma in situ.

genital tract. One patient had synchronous carcinomas in situ of the vulva, vagina, and cervix. A second patient had synchronous malignant Brenner tumor of the ovary, leiomyosarcoma of the uterus, and carcinoma in situ of the cervix. A third patient initially had synchronous invasive cancers of the vagina and the vulva successfully treated with radiation therapy but died of ovarian carcinoma that occurred 21 years later. Eight patients (18%) had an additional nongynecologic malignancy; bladder (one), breast (three), colon (two), lymphoma (one), and melanoma (one). Twelve patients died of gynecologic malignancies (52% of all patient deaths); and five patients died of nongynecologic malignancies.

Metachronous pelvic malignancies. Metachronous pelvic malignancies occurred in 85 patients (Table II). Cervical cancer was the primary malignancy in 67 patients (79%). Again, malignancies of the lower genital tract predominated; 63 patients (74%) had cancers restricted to this region. Three of the seven patients with vulvar cancer developed cervical cancer at a mean interval of 8 years. Three of the four patients with primary vaginal cancer who developed a second malignancy did so in the lower genital tract. Eleven patients with cervical cancer had vulvar cancers, and 44 patients with cervical cancer had vaginal cancers as the second primary cancer, with a mean interval of 11.8 and 8.5 years, respectively, between the first and second diagnosis.

Endometrial cancer occurred in nine patients at a mean interval of 10 years subsequent to a diagnosis of cervical cancer treated with radiation therapy alone. Three patients with ovarian carcinoma, one of whom had endometrioid histologic findings treated with oophorectomy alone, developed endometrial cancer.

Although in situ lesions made up one of the malignancies in 42 of 63 patients (66%) with multiple primary cancers limited to the lower genital tract, there was no statistically significant difference in the interval between first and second cancers for invasive versus in situ lesions.

One patient with a triple gynecologic malignancy consisting of an adenocarcinoma of the uterus and a squamous cell cancer of the cervix treated surgically developed squamous cell cancer of the vagina 21 years later.

Eight patients (9%) had a third primary cancer outside the pelvis; bladder (two), breast (one), colon (three), larynx (one), and lymphoma (one). One of these patients had four primary cancers involving the cervix, vulva, colon, and larynx, with 27 years between her first and fourth cancer diagnosis.

CIS = Carcinoma in situ; NOS = not otherwise specified.
*All lesions are invasive unless specified carcinoma in situ.

Twenty-three patients died of their gynecologic malignancies (69% of all patient deaths), and five deaths were from nongynecologic malignancies.

The cumulative risk for second gynecologic malignancies is summarized in Table III. Malignancies of the lower genital tract statistically increased; 9.6% of patients with vaginal cancer, 4.3% of patients with vulvar cancer, and 1.6% of patients with cervical cancers developed second malignancies of the lower genital tract. In addition, ovarian and uterine malignancies are statistically associated.

Demography. No difference was noted between the age of patients with multiple cancers and those with a single cancer. A review of past medical histories revealed no significant prior diseases compared with the general population. Although 25% of patients reported a family history of cancer, information concerning the degree of kinship was incomplete, and the significance of this is not known.

Prior radiation therapy. None of the patients with synchronous cancer had prior radiation therapy. However, 41 of 85 patients (48%) with metachronous tumors had had prior radiation therapy. Thirty-six of the 41 patients (88%) had the second malignancy 5 years or more after radiation therapy, a time interval considered critical in relation to the carcinogenic risk of ionizing radiation. However, statistical analysis did not associate prior radiation therapy with a subsequent malignancy except in three of the 26 tumor combinations (11.5%) (Table IV). Of these, two tumor combinations (cervical carcinoma in situ: vulvar carcinoma in situ and cervical carcinoma in situ: uterus) were increased by prior radiation therapy, and one tumor combination (cervical: vagina) was decreased. In two of 41 patients (4.9%), radiation therapy was statistically associated with an increase in second malignancy. Of the five metachronous pelvic nongynecologic malignancies (colon three and bladder two), no difference in prior radiation was noted.

Therapy and survival. Ninety-six percent of patients with synchronous multiple cancers and 32% of patients with metachronous multiple cancers received therapy for both malignancies at The Ohio State University. Standard therapies including surgery and radiation

therapy were used. The presence of multiple or subsequent malignancies did not alter the type of therapy chosen, unless prior radiation precluded radiation.

Mortality rates were determined by the most virulent of the synchronous tumors. Patients with metachronous cancers usually were cured of their primary neoplasm, and the mortality rate was determined by the second malignancy and generally conformed to standard survival figures.

Comment

Despite numerous clinical observations,[3,4,6-10] few authors have statistically evaluated multiple gynecologic malignancies. Arneson and Schellas[4] and Morton and

Villasanta,[4] both of whom studied patients with cervical cancer, noted no increase in second primary malignancies of the genital tract, but they relied on an average patient age and years of follow-up, a statistic now considered obsolete.

Axelrod et al.,[10] using the person-years approach,[13] studied 36 patients with double gynecologic primary malignancies and 42 patients with a gynecologic primary tumor and a nongynecologic second primary tumor. They observed a statistically increased incidence of a second gynecologic malignancy but no increased incidence of nongynecologic tumors except for carcinoma of the cervix and secondary lung or oropharyngeal cancers. This correlation between cancer of the cervix and cancer of the oral cavity, lung, and bladder has been evaluated by Newell et al.[16] and has been shown to be related to cigarette smoking.

Kapp et al.,[9] again applying the person-years statistic to patients with a prior diagnosis of cervical cancer, noted an increased incidence of malignancies of the lower genital tract, as well as lung malignancies, and in small numbers of patients, laryngeal and bone cancer. They noted no increase in nongynecologic pelvic cancers subsequent to prior radiation therapy and concluded that radiation is not an etiologic agent. However, since 93% of their patients received radiation, they were not able to compare different treatment regimens with respect to second primary malignancy rates.

Our results imply that the diagnosis of a patient with a malignancy of the lower genital tract identifies a person at a statistically increased risk for a second such malignancy. Our patients who had 9.6% vaginal, 4.3% vulvar, and 1.6% cervical cancers developed a second malignancy of the lower genital tract. The lack of statistical association with other cancers suggests that the most likely etiologic factor is not a genetic, immunologic, or other systemic factor, since such a defect would result in a generalized increased rate of malignancy. Most likely, the increased risk of a second malignancy of the lower genital tract is related to an environmental factor affecting a field of squamous epithelium as theorized by Newman and Cramer[17] in 1959 and Marcus[2] in 1960. Although not addressed in this study, current evidence suggests the human papilloma virus may be such a carcinogenic environmental factor.[18]

Multiple malignancies of the upper genital tract (uterus and ovaries) were shown to be statistically significant in the occurrence of synchronous tumors but not of metachronous tumors. These findings may simply represent the management of the primary disease with surgical extirpation of the uterus, tubes, and ovaries. In contrast to the findings of McDonald et al.,[6] only one of 12 endometrial tumors was associated with a stromal ovarian neoplasm, and in contrast to expected findings in this patient, it was an androgenic tumor. Recently, Woodruff et al.[19] updated their report on synchronous uterine and ovarian cancers. The authors proposed that based on improved survival such tumor combinations represented a multifocal process rather than metastatic disease.

High-dose therapeutic radiation was originally suggested as a carcinogenic agent in uterine sarcoma by Jacox in 1939, in endometrial carcinoma by Zuspan in 1955, and in pelvic girdle sarcoma by Block in 1962. Subsequent reports supported these observations. Statistical analysis of radiation therapy–induced malignancies is limited to four papers. Czesnin and Wronkowski[6] noted a statistically increased incidence of uterine sarcoma and cutaneous malignancies but no endometrial cancers or pelvic girdle sarcoma. As previously noted, Kapp et al.[8] showed an increased risk of lower genital tract, lung, oropharyngeal and bone malignancies. Both of these authors studied patients with cervical cancer after irradiation, but neither compared their results with patients with cervical cancer treated without radiation. Bailar[20] noted an excess of observed over expected cancers for both irradiation and nonirradiation treatment groups with a relatively greater excess in patients treated surgically when compared with those treated by either radiation or radiation plus surgery. In an international collaborative study, Boice et al.[21] showed that second cancers occurred only slightly more frequently (5%) at all sites than expected in 82,616 patients treated for cervical cancer with radiotherapy. With respect to second gynecologic malignancies, uterine and ovarian cancers were not increased, and other genital malignancies occurred at a statistically increased rate, irrespective of mode of primary therapy (surgery or radiation). We find very little evidence that second malignancies (4.9%) are statistically increased by prior radiation.

In our analysis, the prognosis in patients with multiple gynecologic malignancies does not appear to be worse. Management was only altered if prior radiation therapy had been used.

In conclusion, patients with gynecologic malignancies of the lower genital tract are at increased risk for secondary tumors of the lower genital tract, both initially and subsequently. They should be thoroughly evaluated at initial presentation and require lifelong follow-up.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

The results of cryosurgical treatment of cervical intraepithelial neoplasia at one, five, and ten years

J. L. Benedet, M.D., D. M. Miller, M.D., K. G. Nickerson, M.D., and G. H. Anderson, M.B., B.S.

Vancouver, British Columbia, Canada

The results after cryosurgical treatment of cervical intraepithelial neoplasia at 1, 5, and 10 years are reported. Ninety-four percent of the 1675 patients eligible for assessment at 1 year were successfully treated, with only 5.6% lost to follow-up. After 5 years, 14% of patients were lost to follow-up, but the corrected success rate remained essentially unchanged. No major differences in success rates were noted for the various histologic grades of cervical intraepithelial neoplasia treated. A small but definite percentage of patients developed further disease over the ensuing years, indicating the need for long-term, continued surveillance of these patients. (Am J Obstet Gynecol 1987;157:268-73.)

Key words: Cryosurgery, cervical intraepithelial neoplasia, cryosurgery treatment results

The revival in the early 1970s of colposcopy as a diagnostic technique for the evaluation of patients with abnormal Papanicolaou smears revolutionized the treatment of preinvasive cervical neoplasia. Traditionally, cervical cone biopsy and often simple hysterectomy were the mainstays of treatment. The method selected usually depended on the patient's desire for further pregnancies. Because colposcopy permitted an accurate assessment regarding the nature of the abnormality of the Papanicolaou smear, as well as outlining the extent and location of the lesion, techniques that destroyed local tissue came to be used more frequently. Of these, cryotherapy emerged as the most commonly used method to treat cervical intraepithelial neoplasia, particularly in North America. In 1980, Richart et al.[1] estimated that more than 8000 gynecologists in the United States alone had been enrolled in courses dealing with colposcopy and cryotherapy, which indicates a widespread interest in the use of these techniques.

Numerous publications[2-9] have appeared in the literature that report the results of cryotherapy for the treatment of cervical intraepithelial neoplasia, but few reports[1] are available about its intermediate and long-term effects. Our initial experience[10] with cryotherapy in a selected group of patients was encouraging and led to increased use because of rising incidence rates for preclinical cervical carcinoma in young women.[11] The purpose of this study was threefold: (1) to report our subsequent results, (2) to determine if increased use of this technique led to a change in effectiveness, and (3) to report the treatment results at 5 and 10 years after cryotherapy. We were particularly interested in trying to determine what proportion of patients developed further cervical neoplasia after apparent initial success with this treatment.

From the Department of Obstetrics and Gynaecology, Faculty of Medicine, University of British Columbia, Vancouver General Hospital, and the Divisions of Gynaecologic Oncology and Pathology, Cancer Control Agency of British Columbia.

Received for publication December 11, 1986; revised March 31, 1987; accepted April 9, 1987.

Material and methods

The records of all our patients treated for cervical intraepithelial neoplasia with cryotherapy at the Vancouver General Hospital since 1973 were reviewed. Although the merits of the cervical intraepithelial neoplasia system of classification for intraepithelial lesions were recognized, we have also continued to report histologic diagnosis by degree of dysplasia to maintain consistent data recording for statistical and analytic purposes at our institution. The correlation between the two systems we have used is as follows: cervical intraepithelial neoplasia I, mild dysplasia; cervical intraepithelial neoplasia II, moderate dysplasia; and cervical intraepithelial neoplasia III, severe dysplasia or carcinoma in situ. All patients had pretreatment colposcopic assessment and directed biopsy. After correlation of the patient's cytologic findings, colposcopic impression, and directed biopsy findings, a treatment recommendation was made. Patients with a squamocolumnar junction that was entirely visible with no endocervical extension of disease were considered candidates for cryosurgical treatment. A Krymed cryosurgery unit (Model MT600) with nitrous oxide as a refrigerant was used in all cases. This equipment

produces a probe-tip temperature of approximately −83° C. The cryosurgical probes used were selected to correspond to the lesion size, and most patients were treated with a mean active freeze time of 3 to 4 minutes. In a few instances, patients with extensive lesions were treated either with two treatment sessions or with several overlapping freezes at a single session. The main criteria used to determine the effectiveness of the freeze at the time of treatment was the extension of the ice ball 3 to 4 mm beyond the periphery of the lesion.

Patient follow-up consisted of visits at 3- to 4-month intervals for colposcopic examination and repeat Papanicolaou smears. Biopsies of any persistent lesions or suspicious areas were also carried out. If the cytologic findings of the patient's cervical smear and the colposcopic appearance of the cervix were normal after 1 year of follow-up (a minimum of three negative smears), she was then discharged from the clinic to the care of her family physician for cervical cytologic examination on a 6-month basis. All Papanicolaou smears in the Province of British Columbia are examined by a single, central cytology laboratory, and further access to patient records and Papanicolaou smear reports was readily available through the laboratory computer system.

Treatment was defined as successful when a patient had normal cervical cytologic and colposcopic findings 1 year after treatment. Recurrent disease was defined as the development of a new squamous cell neoplasm after 1 year of normal cytologic and colposcopic follow-up.

The data were analyzed by means of Pearson's χ^2 test.

Results

The number of patients treated during the two time periods with the success and failure rates, as well as the number and percentage of patients lost to follow-up at 1 year, is presented in Table I. Slightly more than twice as many patients were treated during the second, more recent, and shorter time period, which illustrates the increased use and confidence in cryotherapy as a treatment modality. In addition, the proportion of patients with cervical intraepithelial neoplasia III (severe dysplasia—carcinoma in situ) treated decreased from 71% to 60%. This change was simply because more patients with cervical intraepithelial neoplasia I (mild dysplasia) and II (moderate dysplasia) were treated in the latter time period rather than a decrease in the incidence rate of in situ carcinoma in our population. No apparent difference was noted in the success or failure rates between the two time periods under review.

The age distribution for all patients in the study is listed in Table II. Eighty-three percent of patients were 30 years of age or younger when treated.

Tables III through V present the results of cryosurgical treatment for all patients available for assessment at 1, 5, and 10 years, respectively. The success rates for the various degrees of dysplasia at any time period are similar with no statistically significant differences. The overall success rate at 1 year was 94.3%. The corresponding rates for all patients at 5 and 10 years were 89% and 85%, respectively. At 1 year, only 5.6% of patients were lost to follow-up, but this increased to 28.8% by 10 years.

All patients who were eligible for 5 or more years of follow-up and in whom the treatment was judged to be unsuccessful were analyzed as to the specific years at which they were noted to have recurrent disease. These results are presented in Table VI. Most treatment failures occurred in the first year and are best classified as primary failures, since they probably reflect cryotherapy's inability to eradicate disease in the first instance. It is also likely that several of the patients in whom the treatment failed in the second year were not truly cured of the disease initially, since some had mild cytologic atypicalities on Papanicolaou smears, which led to their continued surveillance through the Colposcopy Clinic and subsequent diagnosis of persistent dysplasia or carcinoma in situ. Table VI also shows cumulative failure rates by year for these patients. Approximately 6% of patients were considered treatment failures by year 1, and over the ensuing 7 years an additional 4.5% of the patients developed further disease.

The rate of new disease per thousand woman-years was calculated as 5.0/1000. This rate is similar not only to that noted for cone biopsy (5.3/1000) in an earlier study,[12] but also to the incidence rate for preinvasive cervical neoplasia in screened women under the age of 40 years in our province (5.41/1000).

The histopathologic diagnosis noted at the time the patients were found to have recurrent disease was then compared with the initial biopsy diagnosis, and these results are shown in Table VII. One patient treated for squamous carcinoma in situ had an abnormal Papanicolaou test at 6 years that showed suspicious gland cells and was found to have invasive adenocarcinoma of the endocervix. The histopathologic diagnosis in 71 of the remaining 80 patients was similar to the initial pathologic diagnosis. In six of the remaining nine patients, the pathologic diagnosis of the recurrence was more than one grade of dysplasia higher than the initial pathologic diagnosis, which indicates possible progression of disease. In three of these patients, the more advanced pathologic diagnosis was noted within the first year of treatment and may represent a diagnostic error rather than true progression. In two patients treated for moderate dysplasia, recurrences were noted at 3 and 5 years and both were carcinoma in situ.

Except for one patient who was admitted to the hos-

pital 6 days after treatment because of vaginal bleeding caused by an infected cervix, no major complications of treatment were recorded. A degree of menstrual-like cramps was present in virtually all patients during treatment, but this was transient and subsided rapidly on completion of treatment. This was not of sufficient severity in any patient to warrant termination of the procedure. No pretreatment medication with either analgesics, tranquilizers, antispasmodics, or nonsteroidal anti-inflammatory agents was used. Facial flushing also occurred after treatment in most patients but was short-lived.

Lost to follow-up

Although many of the patients in this study were known to have had successful uncomplicated pregnancies after treatment, the data recorded for this particular study did not enable an accurate assessment of fertility and obstetric performance after cryotherapy.

Comment

During the past decade, numerous reports[1, 4-10] have appeared in the literature attesting to the validity of the work of Crisp et al.[2, 3] in the use and effectiveness of cryotherapy as a treatment modality for cervical intraepithelial neoplasia. One of the main problems that has been noted is the difficulty in obtaining long-term treatment results because of poor patient compliance for follow-up.

The results of this study indicate that cryotherapy was effective treatment for patients with cervical intraepithelial neoplasia. All but 6% of patients were available for follow-up at 1 year. The results appeared to be equal for the various types of lesions treated, since it did not appear that histologic diagnosis was a major factor in determining success or failure with this method. The relative importance of lesion size or histologic diagnosis as to which is the more important determinant of success is as yet unresolved. Most studies[13-15] have shown that the severity of cervical intraepithelial neoplasia is a factor, but only a few studies have actually assessed lesion size and histologic diagnosis both as independent and covariables.

This study also demonstrated the difficulty in maintaining patient follow-up records over an extended period. Patients with these lesions tend to be young and are often unmarried; with time, they marry, change their names, and move, particularly in times of high unemployment, thus making follow-up extremely difficult. Nonetheless, the results in the 725 patients who were followed up for 5 years were encouraging, since the success rate remained high and only a few patients developed further disease after the first 2 years. Most treatment failures occurred within the first 2 years of treatment, although a small but definite percentage of patients continued to fail after this time. For some patients, these failures are secondary and probably represent a new focus of disease. These findings serve to emphasize that these patients must still be considered at risk for further disease and thus require close surveillance indefinitely.

We believe that the success rate achieved in this series is because of careful patient selection and meticulous technique in carrying out this treatment. No significant endocervical extension should be present, all margins of the lesion seen should be visible, and good probe application is necessary, with an adequate ice ball formed that extends 3 to 4 mm beyond the edge of any lesion identified. It is also imperative to maintain adequate pressure in the system so that a good ice ball is rapidly formed and maintained.

Although no patients in this study developed invasive squamous cell carcinoma during the years under review, caution must be exercised in interpreting these findings, since the natural history of cervical neoplasia suggests a long latent period between in situ and invasive carcinoma in most instances. Sevin et al.[16] and Townsend et al.[17] have reported the occurrence of invasive carcinoma of the cervix in patients treated with cryosurgery. Most of these cases, however, suggest inadequate pretreatment evaluation rather than cryosurgery causing rapid disease progression. These factors underline the need for careful, meticulous, and expert pretreatment assessment if such problems are to be minimized.

The advantages of cryotherapy are numerous; not only is it an extremely effective treatment method for cervical intraepithelial neoplasia, but it is easy to use, is well tolerated by patients, has minimal side effects or complications, requires no analgesia or anesthesia, and is relatively inexpensive. Despite these advantages, enthusiasm for laser therapy appears to be overshadowing the use of cryotherapy, with an ever-increasing number of physicians learning the techniques of laser surgery.

In regional referral centers and large hospital-based treatment clinics, the ability to use all treatment modalities becomes desirable given the number and range of patients managed in such units. Physicians seeing smaller numbers of patients should be encouraged to continue with cryosurgery given the satisfactory results that can be obtained. The additional expense of laser equipment should be carefully weighed against its potential advantages in a given practice situation. Cryotherapy has the additional advantage of being odorless and does not require expensive ancillary equipment for the evacuation of smoke and odor, which is impor-

tant where space is limited and ventilation and air-conditioning systems are less than ideal.

Schuurmans et al.[18] have reported excellent results with electrocautery as an outpatient treatment modality without anesthesia. Even though this is the simplest and least expensive method, it has been largely overshadowed by cryotherapy. Similarly, we suspect that cryotherapy, in turn, will be replaced by laser surgery.

We extend our appreciation to Mr. Andrew Coldman, Division of Epidemiology, Biometry and Occupational Oncology, Cancer Control Agency of British Columbia, for his assistance with the statistical analysis of the data.

Host defense during pregnancy: Neutrophil chemotaxis and adherence

Peter J. Krause, M.D., Charles J. Ingardia, M.D., Linda T. Pontius, B.S., Harry L. Malech, M.D., Tina M. LoBello, B.A., and Eufronio G. Maderazo, M.D.
Hartford and New Haven, Connecticut

Pregnancy is associated with impairment in several immunologic functions that effect the outcome of certain infectious and autoimmune diseases. Previous studies have indicated that pregnant women have decreased neutrophil motility, but results are discordant. We performed a longitudinal study of polymorphonuclear leukocyte chemotaxis using a micropore filter assay and polymorphonuclear leukocyte adherence using a nylon wool column assay in 58 women during pregnancy, delivery, and the postpartum period. Polymorphonuclear leukocyte chemotaxis was decreased significantly in pregnant women during the second (−20%) and third (−17%) trimesters and 1 to 3 months post partum (−18%), but not during the first trimester (−6%) compared with nonpregnant control subjects. The impairment in polymorphonuclear leukocyte chemotaxis appeared to be a cell-associated rather than a humoral defect. Polymorphonuclear leukocyte adherence was decreased significantly in pregnant women during the third trimester (−16%). These data may help explain the increased incidence of infection and amelioration of certain immunologically mediated illnesses during pregnancy. (Am J Obstet Gynecol 1987;157:274-80.)

Key words: Neutrophil, chemotaxis adherence, pregnancy

Pregnancy is associated with suppression of a wide range of immunologic functions that are thought to effect the outcome of certain infectious and autoimmune diseases.[1,2] Studies done in the preantibiotic era suggested that pregnant women had more severe pneumococcal pneumonia than men or nonpregnant women.[3,4] Pyelonephritis, disseminated gonococcal infection, and *Listeria monocytogenes* bacteremia have been reported to be more common in pregnant than nonpregnant women.[5-8] Women with rheumatoid arthritis and other collagen vascular diseases often have an amelioration of their illnesses during pregnancy.[9] Polymorphonuclear leukocytes are thought to play an important role in the pathogenesis of these illnesses. Normal accumulation of polymorphonuclear leukocytes in an inflammatory site is of critical importance for eradication of bacterial infection and is dependent on normal functioning of polymorphonuclear leukocyte adherence and motility. Several in vitro studies suggest that there is impairment of polymorphonuclear leukocyte motility during pregnancy but results are discordant and there is little information on possible etiologic mechanisms.[10-13] We studied polymorphonuclear leukocyte chemotaxis and adherence in 58 women during pregnancy and delivery and 1 to 3 months post partum and in healthy, nonpregnant control subjects. Significant polymorphonuclear leukocyte chemotactic and adherence defects were noted during the second and third trimesters of pregnancy and in the immediate postpartum period. Data are presented suggesting that the chemotactic defects are the result of cellular rather than serum abnormalities.

Material and methods

Study subjects. Blood was obtained from healthy, pregnant women who attended an obstetric clinic during the first (0 to 14 weeks), second (15 to 28 weeks), and third (29 to 40 weeks) trimesters and 1 to 3 months post partum. Women with chronic illness or taking medication other than vitamins were excluded from the study. Blood was simultaneously obtained and tested in healthy, nonpregnant subjects of comparable age who were taking no medication. Informed consent to obtain blood was obtained in all cases in accordance with hospital institutional review guidelines.

Preparation of polymorphonuclear leukocytes and serum. Blood obtained from study subjects was heparinized with preservative-free sodium heparin (Fisher Scientific Co., Pittsburgh, Pennsylvania; 50 U/ml blood) and sedimented with 6% hetastarch in saline solution

(5 parts whole blood/1 part hetastarch) at room temperature for 15 to 30 minutes. The leukocyte-rich plasma was centrifuged at low speed (500 × g). The pellet was washed with Medium 199 and then resuspended to a concentration of 5×10^5 polymorphonuclear leukocytes/0.7 ml. The chemotactic factors used in these studies were zymosan-activated serum derived from the incubation of healthy, nonpregnant adult serum with zymosan (5 mg/ml serum) at 37° C for 30 minutes or *N*-formyl-methionylleucyl-phenylalanine (FMLP).

Polymorphonuclear leukocyte locomotion assay. A micropore filter assay was employed using modified Boyden chambers (Ahlco Corp., Southington, Connecticut) as described previously.[14] A polymorphonuclear leukocyte suspension of 5×10^5 cells/0.7 ml Medium 199 was placed in the upper compartment and a chemoattractant was introduced into the lower compartment of the Boyden chamber. The lower compartment contained Medium 199 to test chemokinetic responses of 3% zymosan-activated normal serum or 10^{-8} mol/L FMLP to test chemotactic polymorphonuclear leukocyte responses. In other experiments, serum was placed in the upper compartment of the Boyden chamber to test for the possibility of a cell-directed inhibitor.

The polymorphonuclear leukocytes were allowed to partially penetrate a 13 mm diameter, 5 μm pore size cellulose nitrate filter (Schleicher and Schuell, Inc., Keene, New Hampshire) during a 90-minute incubation period at 37° C in a humid, 5% CO_2 atmosphere. The polymorphonuclear leukocytes were then removed, fixed, stained with hematoxylin, cleared with xylene, and mounted on slides. An automated microsectioning counting technique was used to determine the number of polymorphonuclear leukocyte at 10 μm increments from 20 μm to 120 μm into the filter. Because we used a mixed leukocyte suspension, the first 20 μm of the filter was not examined to avoid inclusion of monocytes and lymphocytes in the cell counts. The mean distance (in micrometers) migrated by the polymorphonuclear leukocytes in 90 minutes of incubation time or locomotion index (LI_{20}) was then determined. A mean LI_{20} value of triplicate determinations was calculated for each blood sample. To minimize filter variability, prepurchase testing of samples of filters from various uncut sheets or lot numbers are performed. Filters from a satisfactory lot are used. Because occasional variations between lots of filters are unavoidable, simultaneous daily testing of healthy adults along with study subjects is always carried out.

Polymorphonuclear leukocyte functional subsets

Micropore filter assay. Differences in motility among polymorphonuclear leukocytes were analyzed by the depth that they reached into the filter. Slow-moving polymorphonuclear leukocytes were arbitrarily defined as those traveling 20 to 60 μm into the filter whereas fast-moving polymorphonuclear leukocytes were those traveling 70 to 140 μm into the filter.

31D8 monoclonal antibody. Polymorphonuclear leukocyte functional subpopulations were also defined with use of the mouse monoclonal antibody 31D8, which binds heterogeneously to polymorphonuclear leukocytes and correlates with polymorphonuclear leukocyte chemotaxis. The methods used for 31D8 labeling and analysis have been described previously.[15, 16] In brief, separated polymorphonuclear leukocytes were washed twice in phosphate-buffered saline solution/bovine serum albumin, counted, mixed with 31D8 antibody, and allowed to incubate on ice for 45 minutes. The polymorphonuclear leukocytes were then washed three times in phosphate-buffered saline solution/bovine serum albumin and incubated for 30 minutes on ice with fluorescein isothiocynate–labeled goat-antimouse IgG. The labeled polymorphonuclear leukocytes were washed three more times in phosphate-buffered saline solution/bovine serum albumin and stored on ice, in the dark, and in the absence of CA^{++} or Mg++ until use. Flow microfluorometry was performed with an EPICS C (Coulter, Electronics Inc., Hialeah, Florida) with an argon laser emitting 500 mW at 488 nm. Forward and 90° light scatter was used to identify the polymorphonuclear leukocyte populations from lymphocytes and monocytes. The fluorescence intensity distribution of 10,000 polymorphonuclear leukocytes was determined. The data were presented as the number of cells on the vertical axis and log green fluorescence on the horizontal axis divided into a three-decade log scale consisting of 255 channels.

Polymorphonuclear leukocyte adherence assay. Polymorphonuclear leukocyte adherence was studied because adherence of polymorphonuclear leukocytes to vascular epithelium is the first step in accumulation of polymorphonuclear leukocytes at an inflammatory site. A well-regulated polymorphonuclear leukocyte adherence is also necessary for normal polymorphonuclear leukocyte chemotaxis.[17] A modification of a previously described nylon wool column adherence assay was used to measure polymorphonuclear leukocyte adherence.[17] Forty milligrams of nylon wool (LeukoPak, Fenwal Inc., Ashland, Massachusetts) was packed to a height of 1.5 cm in a tuberculin syringe without the needle or plunger. Separated polymorphonuclear leukocytes were prepared as described above. An aliquot (0.1 ml) of the polymorphonuclear leukocyte solution was removed for determination of the polymorphonuclear leukocyte count while 1.0 ml was allowed to percolate through the nylon column in the syringe. The effluent was collected, a polymorphonuclear leukocyte count determined, and the percent adherence calcu-

lated according to the formula: percent polymorphonuclear leukocyte adherence = ([original polymorphonuclear leukocyte count − effluent polymorphonuclear leukocyte count]/[original polymorphonuclear leukocyte count]) × 100. Each test was run in triplicate.

Statistical analysis. Significance of differences was evaluated by the Student t test. Linear regression analysis was performed according to standard statistical procedure. A p value <0.05 was considered significant.

Results

Fifty-eight healthy pregnant women were enrolled in the study. Eleven women were studied in all three trimesters, 27 women were studied in at least two trimesters, and 20 were studied in one trimester. Thirteen women were studied at delivery and 21 in the postpartum period. Cord blood samples were obtained from the newborn infants of 13 women. Fifty-two women delivered healthy, term infants. Five infants were premature. There was one miscarriage.

Polymorphonuclear leukocyte chemotaxis. Significant impairment in polymorphonuclear leukocyte chemotaxis was noted in the second and third trimesters of pregnancy, during delivery, and in the postpartum period, but not in the first trimester (Table I). The percentage decrease in polymorphonuclear leukocyte chemotaxis in pregnant women during the second trimester compared with nonpregnant control subjects was −20% with activated normal serum and −18% with FMLP used as chemoattractants. Respective values during the third trimester were −17% for activated normal serum and −8% with FMLP. Polymorphonuclear leukocyte chemokinetic values were not significantly different in pregnant women and nonpregnant control subjects. Results of polymorphonuclear leukocyte chemotaxis and chemokinesis were similar in the 11 women studied in all three trimesters compared with the other 47 women studied in only one or two trimesters (Fig. 1). Further studies indicated that decreased polymorphonuclear leukocyte chemotaxis in pregnant women resulted from cellular rather than humoral abnormalities. No difference in the enhancement of polymorphonuclear leukocyte chemokinesis was observed when serum from pregnant women or nonpregnant control subjects was incubated with polymorphonuclear leukocytes in the upper compartment of the Boyden chamber. These data indicate that a cell-directed inhibitor did not contribute to decreased polymorphonuclear leukocyte chemotaxis during pregnancy. Similarly, there was no evidence of chemotactic factor inactivator activity in serum from pregnant women. Generation of complement-derived chemotactic activity was similar in serum from pregnant women and nonpregnant control subjects as shown by similar polymorphonuclear leukocyte chemotactic values when zymosan-activated serum from pregnant (53.3 ± 15.1 μm) or nonpregnant (58.3 ± 14.1 μm) subjects was placed in the bottom compartment of the Boyden chamber.

Polymorphonuclear leukocyte functional subsets

Micropore filter assay. Analysis of the distribution of polymorphonuclear leukocytes at different distances into the micropore filter in both pregnant and nonpregnant women shows a heterogeneous polymorphonuclear leukocyte chemotactic response (Fig. 2). Pregnant women had a higher percentage of polymorphonuclear leukocytes moving 20 to 70 μm into the filter (81%) than had control subjects (69%; $p < 0.01$). The size of the "slow" population of polymorphonuclear leukocytes was significantly different between women in the second and third trimesters and post partum compared with control subjects but not for women in the first trimester. We examined the possibility that this population of "slow" cells was immature polymorpho-

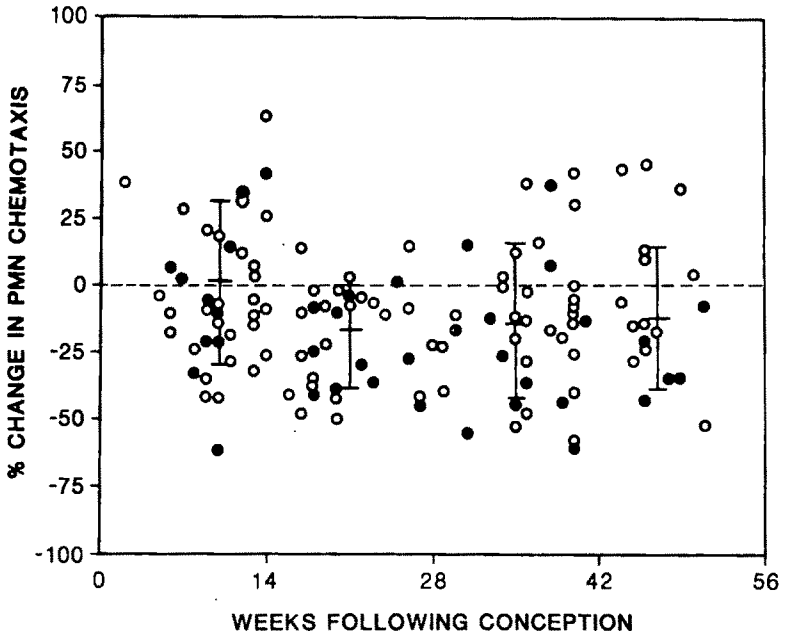

Fig. 1. Percent change in polymorphonuclear leukocyte *(PMN)* chemotaxis in 58 women during pregnancy and the postpartum period compared with 58 nonpregnant control subjects. Mean PMN chemotaxis values using zymosan-activated serum in pregnant women studied in all three trimesters are depicted by *closed circles* and one or two trimesters by *open circles*. The trimesters are delineated as follows: first trimester, 0 to 14 weeks; second trimester, 14 to 28 weeks; third trimester, 28 to 40 weeks, and post partum, 40 to 56 weeks. Mean chemotaxis values ± 1 SD for each trimester are depicted by the *horizontal lines*.

nuclear leukocytes (bands and metamyelocytes) because they are less motile than mature cells. There was a significantly higher percentage of immature polymorphonuclear leukocytes in pregnant women than in nonpregnant control subjects during the third trimester (20.6% ± 8.9% and 5.6% ± 2.3%, respectively; $p < 0.01$) but not during the other two trimesters when compared with control subjects.

31D8 monoclonal antibody–binding assay. To further study the heterogeneous chemotactic response noted with the micropore filter assay, we used immunoglobulin G mouse monoclonal antibody (31D8), which binds heterogeneously to polymorphonuclear leukocytes from the peripheral circulation and correlates with polymorphonuclear leukocyte functional heterogeneity.[15, 16] Polymorphonuclear leukocytes from seven women studied on at least two separate occasions during pregnancy and post partum and nonpregnant control subjects were labeled with 31D8. The majority of polymorphonuclear leukocytes strongly bound 31D8 (31D8 "bright") and generated a highly fluorescent peak. The remaining polymorphonuclear leukocytes weakly bound 31D8 (31D8 "dull") and generated a contiguous, smaller, less fluorescent area to the left of the major peak. 31D8 "bright" cells depolarize, reduce nitroblue tetrazolium, and migrate chemotactically when stimulated with the chemoattractant FMLP, whereas 31D8 "dull" cells fail to respond similarly.[15, 16] The number of polymorphonuclear leukocytes in pregnant women and control subjects that strongly bound 31D8 were quantitated as described previously. No significant differences were noted in 31D8 binding during pregnancy (88.5% ± 5%) compared with control subjects (87.6% ± 4%), nor were any differences noted for any of the trimesters. These data indicate that the differences in the heterogeneous polymorphonuclear leukocyte chemotactic response noted with the micropore filter assay between pregnant women and nonpregnant control subjects was not a result of differences in the amount of 31D8 polymorphonuclear leukocyte antigen.

Polymorphonuclear leukocyte chemotaxis in pregnant women and their newborn infants. Cord blood was obtained from 13 newborn infants whose mothers were enrolled in the study. Mean polymorphonuclear leukocyte chemokinetic and chemotactic values for the newborn infants were 34.3 ± 9.9 μm and 38.6 ± 12.7 μm, respectively, compared with values of 35.8 ± 5.7 μm ($p = 0.63$) and 53.5 ± 8.1 μm ($p = 0.001$), respectively, in their mothers during pregnancy. Linear regression analysis was used to determine whether infants born to mothers with high polymorphonuclear

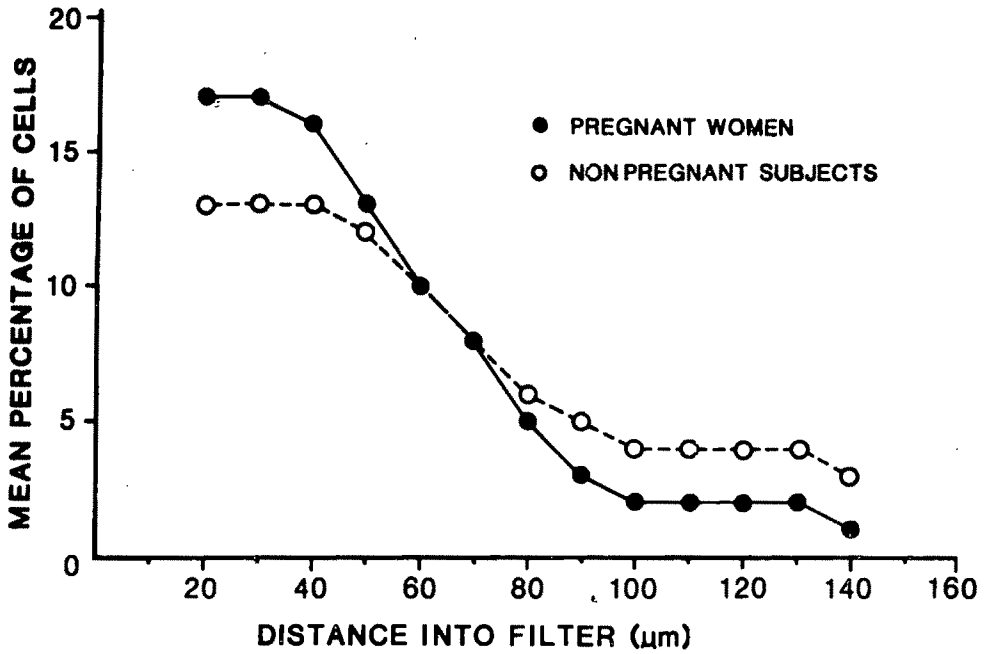

Fig. 2. The heterogeneity of polymorphonuclear leukocyte chemotaxis in the 11 pregnant women studied in all three trimesters of pregnancy and in 11 nonpregnant subjects. The mean percentage of cells that moved into the filter from women during the second trimester of pregnancy are shown.

leukocyte motility values relative to other mothers had high polymorphonuclear leukocyte motility values relative to other infants. No such relationship was found with either polymorphonuclear leukocyte chemokinesis ($r = -0.13$; $p = 0.66$) or chemotaxis ($r = 0.48$; $p = 0.10$).

Polymorphonuclear leukocyte adherence. Mean polymorphonuclear leukocyte adherence values were significantly decreased during pregnancy (76.8% ± 18.4%; $n = 45$) compared with healthy control subjects (86.2% ± 13.8%; $n = 45$; $p < 0.01$). Although mean polymorphonuclear leukocyte adherence values during each trimester and post partum were decreased compared with those of nonpregnant control subjects, it was only during the third trimester that the difference between values in pregnant women (75.0% ± 20.3%; $n = 16$) and nonpregnant control subjects (88.8% ± 12.0%; $n = 16$; $p = 0.03$) were significant.

Comment

The results of this study clearly indicate that there is a significant decrease in polymorphonuclear leukocyte chemotaxis and adherence during the latter part of pregnancy. A well-regulated chemotaxis and adherence enable polymorphonuclear leukocytes to move rapidly from the vascular compartment to the peripheral tissue.[17] Polymorphonuclear leukocytes are thought to be of central importance for both eradication of invasive bacterial pathogens and tissue damage that occurs in several connective tissue disorders. Miles et al.[18] have shown that delay of delivery of polymorphonuclear leukocytes to infected tissue for as little as 2 to 4 hours may prevent the eradication of a focus of infection in spite of eventual accumulation of polymorphonuclear leukocytes as shown by pus formation. The unit of measure of polymorphonuclear leukocyte chemotaxis used in this study (LI_{20}) is the average distance traveled by all the polymorphonuclear leukocytes. Therefore, small numeric differences in the LI_{20} may represent large functional differences in polymorphonuclear leukocyte chemotaxis. Several studies have indicated that lysosomal enzymes and other mediators of inflammation released by polymorphonuclear leukocytes are important causes of rheumatoid inflammation.[19, 20] Our results may therefore help explain the increased severity of several infectious diseases in pregnant women, including gonorrhea, listeriosis, pneumococcal pneumonia, scarlet fever, typhoid fever, diphtheria, septic shock, and pyelonephritis,[1-8] as well as the improvement in symptoms of illnesses such as rheumatoid arthritis and ankylosing spondylitis.[9]

Previous studies of polymorphonuclear leukocyte function during pregnancy have averaged polymorphonuclear leukocyte chemotactic values from different subjects over several months rather than weekly, have not followed the same pregnant women through-

out pregnancy, and have used different assays of polymorphonuclear leukocyte chemotaxis than in our study.[2, 10-13] Nonetheless, our findings of normal polymorphonuclear leukocyte chemotaxis during the first 14 weeks of gestation and decreased polymorphonuclear leukocyte chemotaxis during the subsequent 26 weeks of gestation and for 3 months post partum are similar to those of Bjorksten et al.[10] and Cotton et al.[11] They are also compatible with clinical observations that the greatest severity of certain bacterial infections occur during the latter half of pregnancy.[2-4]

The mechanism(s) of decreased polymorphonuclear leukocyte chemotaxis during pregnancy is unclear. Our results indicate that a cell-associated rather than a serum factor accounts for impaired polymorphonuclear leukocyte chemotaxis in pregnant women. These results are concordant with most previous studies, although the gentle washing used in polymorphonuclear leukocyte isolation procedures may not be sufficient to clear a serum inhibitor. The absence of a diffusable chemotactic inhibitor would help explain why no correlation was noted between the magnitude of impairment of chemotaxis in pregnant women and in their newborn infants. Although previous studies suggest that a cell-associated defect is responsible for decreased polymorphonuclear leukocyte chemotaxis during pregnancy, no specific polymorphonuclear leukocyte defect has as yet been identified in pregnant women.

Previous studies have shown that mature polymorphonuclear leukocytes are not functionally homogeneous. A heterogeneous chemotactic response has been noted among polymorphonuclear leukocytes that appear mature by light microscopy, with approximately 60% to 80% of cells being classified as fast movers and the rest as slow movers.[15, 16, 21] There was a larger percentage of less motile polymorphonuclear leukocytes in pregnant women in the second and third trimesters and in the postpartum period compared with nonpregnant control subjects. This could not be completely explained by differences between the two groups in percentages of immature polymorphonuclear leukocytes because a significant difference in band and metamyelocyte counts was noted only during the third trimester. The monoclonal antibody 31D8 was used to investigate another possible explanation for the increase in less motile polymorphonuclear leukocytes in women during the last two trimesters of pregnancy. Recent studies suggest that the 31D8 monoclonal antibody can detect specific polymorphonuclear leukocyte functional subpopulations derived from different progenitor cells in the bone marrow.[16] No significant difference in antibody binding to polymorphonuclear leukocytes from pregnant women and nonpregnant control subjects was found, however.

Another cell-associated defect that could account for decreased polymorphonuclear leukocyte chemotaxis during pregnancy is polymorphonuclear leukocyte adherence because polymorphonuclear leukocyte chemotaxis is dependent on a well-regulated adherence.[17] Polymorphonuclear leukocyte adherence was decreased in pregnant women during the third trimester. Because polymorphonuclear leukocyte chemotaxis was decreased during the second and third trimesters, impairment of polymorphonuclear leukocyte adherence in pregnant women also does not completely explain the decrease in polymorphonuclear leukocyte chemotaxis.

The results of this study indicate that polymorphonuclear leukocyte chemotaxis is decreased during the second and third trimesters of pregnancy and in the postpartum period whereas polymorphonuclear leukocyte adherence is decreased during the third trimester of pregnancy. These findings might help explain the increased severity of bacterial infections and amelioration of certain collagen vascular diseases during pregnancy. Further studies are needed to elucidate the mechanisms of suppression of polymorphonuclear leukocyte chemotaxis and adherence during pregnancy.

We thank Dr. Charles Woronick, Agnes Reynolds, Charlotte Block, Phyllis Bannon, Claire Eddy, and Patricia Fort for their assistance.

BRIEF SUMMARY

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

February 1987

Varicella zoster antibody testing in the care of pregnant women exposed to varicella

James A. McGregor, M.D.C.M., Saralyn Mark, B.A., Gayle P. Crawford, M.D., and Myron J. Levin, M.D.

Denver, Colorado

Appropriate use of varicella zoster immunoglobulin to prevent or ameliorate maternal or perinatal infection depends on accurate identification of varicella-susceptible women. Detection of fluorescent antibody to varicella zoster virus membrane antigen is an available means for identifying women exposed to varicella who are at risk for infection. During a 5½-year period, 37 pregnant women who had been exposed to varicella and who had a negative or indeterminate history of prior varicella were tested for the presence of varicella zoster virus membrane antigen. Among the 17 women with a negative history, 12 (71%) had a positive test result and five (29%) had a negative test result. Among 20 women with indeterminant histories, 18 (90%) were immune and two (10%) were susceptible. Three additional women who were tested despite a history of varicella had positive varicella zoster virus membrane antigen test results. Overall, 81% of patients with a negative or uncertain history of varicella had serologic evidence of past varicella. One of six untreated seronegative women and one weakly positive woman developed disease. There was no instance of congenital varicella. Expeditious determination of varicella zoster virus membrane antigen or equivalent anti-varicella antibody status in pregnant women exposed to varicella appears to be a rapid, satisfactory method for determining who should promptly receive varicella zoster immunoglobulin passive immunization. (Am J Obstet Gynecol 1987;157:281-4.)

Key words: Varicella, pregnancy, antibody, prevention, serology, immunization

Varicella is an acute, highly contagious, common childhood infection that is increasingly recognized as a potential cause of serious maternal and perinatal morbidity in susceptible pregnant women.[1-3] Varicella in pregnant women may be complicated by preterm labor, pneumonia, and occasionally death.[1-3] Although uncommon, intrauterine infection is associated with stillbirth and stigmata of congenital varicella infection, including mental retardation, microcephaly, blindness, limb hypoplasia, and skin scarring with contractions.[1, 2] Maternal exposure to varicella is not uncommon because of the prevalence of this illness in small children. Past estimates suggest that five cases of varicella or herpes zoster occur per 10,000 pregnancies and that a transplacentally transmitted congenital varicella infection occurs in 5% or less of maternal varicella infections.[3-5] Recent reports indicate that maternal and congenital varicella may be more common than this.[1, 6]

Varicella confers lifelong immunity in immunocompetent hosts. In susceptible individuals, passive immunization with high-titer varicella zoster immunoglobulin given within 96 hours after exposure prevents or ameliorates varicella.[7-9] Although relatively expensive, varicella zoster immunoglobulin is now widely available. Accordingly, passive immunization of susceptible women exposed to varicella is recommended to reduce the risks of maternal and fetal varicella.[9, 10] This represents a change from recommendations made when varicella zoster immunoglobulin was in short supply.

The fluorescent antibody test for varicella zoster virus membrane antigen is a satisfactory means of determining susceptibility to varicella.[11, 12] Recent information suggests that enzyme-linked immunosorbent assay–immunoglobulin G anti-varicella zoster virus serologic testing appears equivalent to varicella zoster virus membrane antigen testing and is easier to perform.[11, 12] Because determination of susceptibility to varicella solely on the basis of a negative history may be unreliable,[8] we evaluated the use of the varicella zoster virus membrane antigen test to determine varicella susceptibility and decide who, among 37 pregnant women with recent exposure to varicella, should receive varicella zoster immunoglobulin.

Material and methods

The exposed pregnant women were seen at the University of Colorado Health Sciences Center between January 1, 1980, and June 13, 1986. Approximately 13,500 deliveries were performed during this period.

From the Department of Obstetrics and Gynecology, University of Colorado Health Sciences Center.

FAMA, varicella zoster virus membrane antigen; V-ZIG, varicella zoster immunoglobulin.

*One patient with varicella pneumonitis, no V-ZIG, >96 hours after exposure.

†One patient given V-ZIG remained well. This is the only patient who received V-ZIG.

‡One patient with positive FAMA who developed mild varicella.

§Includes three patients who underwent FAMA despite history of varicella.

Age, race, socioeconomic status, and obstetric features of these patients were unremarkable. All patients were born in North America. Information concerning past history of varicella, and the timing and type of exposure, was obtained from the patient or other family members. Varicella zoster virus membrane antigen testing was undertaken in 37 women who had had a recent exposure (≤4 days before) and a negative or unknown history of prior varicella. Three additional patients were tested despite a history of varicella. The diagnosis of varicella in the index cases was made on clinical grounds. Varicella zoster virus membrane antigen test procedures, controls, and serologic material were as described elsewhere.[12, 13]

The clinical outcomes of tested women and their newborns were obtained by chart review. Equations derived from Bayes' theorem were used to calculate false negative and positive rates.[13]

Results

Thirty of the 37 (81%) women with negative histories were seropositive, demonstrating forgotten or inapparent prior varicella (Table I). The three women with histories of varicella had positive test results.

Because of restricted supplies, varicella zoster immunoglobulin was not available or recommended for immunocompetent pregnant women during the initial years of this study. Only one seronegative patient received varicella zoster immunoglobulin and she remained well. No infant developed congenital varicella.

Of the 37 patients with negative histories, 12 (32%) had close household contact with infected offspring. Three of these 12 women were actually seronegative (Table II). Among the three seronegative women, only one (33%) developed varicella. Another 21 women were exposed outside their homes to relatives, students, or friends or within the hospital to patients with varicella. Four of these 21 women were seronegative and none developed illness. Thus only one of six (17%) of untreated susceptible pregnant women developed varicella. One woman with a weakly positive test result at 1:2 dilution developed mild, uncomplicated varicella 15 days after a nonhousehold exposure.

A negative history of varicella was unreliable because 81% of such patients had serologic evidence of past varicella. Susceptibility to varicella, as determined by recollection, had a false negative rate of 91% and a false positive rate of 0%. In this clinical setting, varicella zoster virus membrane antigen testing was satisfactory, giving a false negative rate of disease susceptibility of only 16%. A single occurrence of a mild case of varicella in a woman with a weakly positive test result (false positive rate of 50%) was of concern but was not associated with morbidity. These absolute rates are questionable because the numbers are small, exposures were variable, and the population was selected for a negative history of varicella.

Because not all pregnant women with an exposure to varicella were examined serologically during this period, these results should not be considered population based. Nevertheless, the two cases of maternal varicella that occurred at our center during the study were among the 37 tested women who did not have a history of varicella.

Comment

Our findings in pregnant women confirm those of Ross,[8] who showed that approximately 80% of nonpregnant adults with no recollection of varicella are actually immune on the basis of serologic evidence. Ross estimated that only 4% of infections are subclinical. Previously, Ross showed that only 8% of exposed parents with a negative history developed varicella. That

only one of three sero-susceptible women with a household exposure to an infected child developed varicella suggests that pregnant women may not be as susceptible to this infection as are children. Previously, Ross showed that only 8% of exposed parents with a negative history developed varicella. These observations fit with the relatively infrequent occurrence of varicella in pregnant women despite an approximately 10% susceptibility rate in the general population and the anecdotal frequency of maternal exposure to small children with varicella.[14] Subgroups, including immigrants from the Caribbean and the tropics and individuals who were sequestered in childhood, may be at significantly higher risk for acquiring varicella.[14] A negative history of prior varicella is more likely to be reliable within these subgroups.

It should be emphasized that passive immunization in the perinatal setting is aimed primarily at prevention of varicella in the mother and newborn. Because of possible incomplete uptake and transplacental transmission, the newborn of a mother who received varicella zoster immunoglobulin within 5 days before delivery should be passively vaccinated promptly after birth.[9] There is as yet no evidence that passive immunization of varicella virus–susceptible women can prevent intrauterine infection.[9] It is theoretically possible that passive varicella zoster immunoglobulin immunization could modify maternal varicella infection so that it becomes asymptomatic while still allowing transplacental infection.

These results confirm those of Williams et al.[13] showing that varicella zoster virus membrane antigen is sensitive and useful in determining who should receive varicella zoster immunoglobulin. Measurement of varicella zoster virus membrane antigen, or an equivalent test, provides a rapid, practical, and cost-effective means of determining immunity to varicella in exposed pregnant women who give a negative history for prior infection. Direct clinical comparisons with alternative serologic tests, including enzyme-linked immunosorbent assay–immunoglobulin G, remain to be performed.[11, 12]

Although now available for unrestricted use, varicella zoster immunoglobulin remains expensive, costing approximately $75 for a single 125 U vial, with most adult doses totaling at least $375 (one vial for each 10 kg body weight, up to five vials intramuscularly). Laboratory charges for varicella zoster virus membrane antigen are $30 at our institution, so determination of varicella susceptibility is clearly cost-effective because screening can avoid prophylaxis for approximately 80% of exposed individuals with negative or indeterminate histories of past varicella infection. Intramuscular varicella zoster immunoglobulin administration can cause pain and swelling at the injection site, as well as occasional constitutional symptoms and rarely anaphylaxis.[9] Transmission of viral infection, including human immunodeficiency virus (HIV), is not a demonstrated risk.[15]

Serologic testing should be expedited and varicella zoster immunoglobulin given within 96 hours of exposure of seronegative pregnant women to varicella. Although less contagious than varicella, herpes zoster is also a source of varicella zoster virus infection in susceptible individuals. If reliable varicella zoster virus antibody testing is unavailable, pregnant women with a definite negative history of prior varicella infection should be given varicella zoster immunoglobulin. However, it should be realized that the majority of these passive immunizations are unnecessary. Past information suggests that immunocompetent pregnant women with a positive history of past varicella do not require serologic testing or varicella zoster immunoglobulin immunization. In Ross' study[8] of 641 adults exposed to varicella, only one of 475 (0.002%) with a positive history of prior varicella developed disease. As noted, the only cases of maternal varicella seen at our center during the study period did not have a prior history of varicella.

Consideration should be given to routinely obtaining a history of past varicella infection early in pregnancy. Susceptibility of women with a negative history could then be determined serologically and the patient advised; varicella zoster immunoglobulin administration could be expedited if exposure occurs during pregnancy. Availability of a safe and effective varicella zoster virus vaccine would allow for active vaccination of susceptible nonpregnant women, as is done for rubella, and facilitate further reduction of varicella-related morbidity in women as well as their fetuses and newborns.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Sonographic features of the triploid fetus

C. Lockwood, M.D., A. Scioscia, M.D., R. Stiller, M.D., and J. Hobbins, M.D.
New Haven, Connecticut

The sonographic characteristics of six viable triploid fetuses, with gestational ages ranging from 16 to 33 weeks, are presented. Each pregnancy was associated with decreased amniotic fluid volume, a significant lag in biparietal diameter and femur length, and severe head-to-body disproportion. No placental abnormalities were noted on ultrasound and only one placenta demonstrated hydropic change (15% to 20% of villi) on pathologic examination. Since the nonmolar triploid fetus often presents with unexplained intrauterine growth retardation, identification of its characteristic sonographic features allows for karyotype confirmation and the avoidance of inappropriate obstetric management. (AM J OBSTET GYNECOL 1987;157:285-7.)

Key words: Triploidy, partial mole, sonographic findings, head-to-body disproportion

Triploidy is found in 1% of all conceptuses and accounts for 20% of the chromosomal abnormalities identified in spontaneous abortuses.[1] The neonatal incidence of triploidy is 1:2500 to 1:10,000 live births.[1,2] The condition is incompatible with long-term extrauterine survival; rapid postpartum deterioration is the rule. Triploidy associated with partial hydatidiform mole may present as atypical toxemia; alternatively, nonmolar triploidy may be manifested by severe and enigmatic fetal growth retardation. This report describes in detail the sonographic features of the viable triploid fetus in gestations not complicated by obvious partial hydatidiform mole. Recognition of the characteristic sonographic features will enable expeditious karyotype confirmation and appropriate obstetric management.

Material and methods

All diagnoses of triploid karyotype made at the Yale University cytogenetics laboratory between 1984 and 1986 were ascertained. Sources for cell cultures included amniotic fluid obtained by amniocentesis and trophoblasts obtained at the time of pregnancy termination. A total of nine pregnancies had undergone ultrasound examinations, six with viable fetuses and no sonographic evidence of placental molar degeneration and three with sonographic evidence of molar degeneration and either a nonviable hydropic fetus (n = 1) or no identifiable fetal pole (n = 2). Ultrasound evaluations were performed at the Yale University Perinatal Unit and the Bridgeport Hospital Antenatal Testing Unit with a General Electric Model RT3000 (G.E. Corp., Rancho Cordova, California).

Results

Cytogenetic, pathologic, and sonographic data for the six pregnancies accompanied by viable fetuses are presented in Table I. Each pregnancy was associated with decreased amniotic fluid volume, a significant lag in biparietal diameter and femur length, and profound head-to-body (head circumference/abdominal circumference) disproportion. Sonographers also commented on the lack of fetal movement and marked flexion about the spine in Cases 1, 2, and 6.

After amniocentesis, analysis revealed 69,XXX karyotypes for each of the six gestations. No obvious placental cystic change was noted on sonography. Placental pathology reports were available in Cases 1, 2, 3, 5, and 6; hydropic change (15% to 20% of villi) was demonstrated only in Case 3. None of these pregnancies were complicated by toxemia.

In addition, in the three gestations demonstrating obvious placental molar change on ultrasound, the patients presented at 14 to 17 weeks' gestation. In all cases, placental pathologic examination confirmed partial mole. In two cases, a 69,XXY karyotype was identified, with no fetus present in each case (one accompanied by preeclampsia). A hydropic 12-week fetus (crown-rump length) without a heartbeat was identified in a third patient who presented with eclampsia at 14 weeks' gestation; the karyotype was 69,XXX.

Comment

The triploid infant (fetus) is always severely growth retarded with symmetrical shortening of both head size and long bone length.[1] In addition, a significant head-to-trunk disproportion appears to be present.[1] Associated anomalies are variable but can include syndactyly

of the third and fourth digits (61%), congenital heart disease (60%), low-set ears (50%), adrenal hypoplasia (44%), micrognathia (30%), cystic renal dysplasia (26%), colobomas (25%), abdominal wall defects (23%), hydrocephaly–hydranencephaly (18%), neural tube defect (13%), and biliary atresia–gallbladder agenesis (7%).[1] Male infants (69,XXY) have abnormal genitalia (perhaps because of a lack of X chromosome inactivation).[1] Cellular changes include increased nuclear and cytoplasmic volume and a 50% increase in cellular deoxyribonucleic acid content.[1]

The condition arises when an additional haploid complement (n = 23) of chromosomes is present (n = 69). The parental origin of these supernumerary chromosomes is presented in Table II. Approximately 62% of triploid cases have a 69,XXY complement while 37% are 69,XXX; either karyotype may be derived from a maternal or paternal extrahaploid source.[2] The paternally derived 69,XYY karyotype is found infrequently, reflecting a high early loss rate.

The development of placental hydatidiform degeneration–hydropic change is relatively common in triploidy (>50%) while the presence of a partial mole is less frequent.[1] Either trophoblastic abnormality appears to be present in all cases in which there is a paternal origin of the extrahaploid set of chromosomes but is far less common with a maternal origin.[2] The development of toxemia is associated with hydatidiform degeneration–partial mole.

The findings in this small series (confirmed with sonography) illustrate the significant degree of fetal growth retardation present in the triploid fetus. Causes may include an abnormally slow fetal mitotic rate or suboptimal trophoblast nutritional function. While Blackburn et al.[1] described a head-to-trunk discrepancy, implying that the chest is abnormally small, we noted a significant reduction in the abdominal circumference compared with the head circumference. In all five cases where it was recorded, the head circumference/abdominal circumference ratio was greater than the ninety fifth percentile for gestational age (mean 1.53, range 1.89 to 1.31). In the sixth case, marked head-to-body disproportion was observed by the sonographer; however, the abdominal circumference could not be obtained because of marked fetal flexion. Nutritional deficiency with "head sparing," vis-

Abdominal circumference (cm)	*HC/AC and 95th percentile for gestational age†*	*Amniotic fluid volume*	*Placental appearance and grade*	*Maternal complications*	*Comments*	*Placental abnormality*
12.0	1.89 (1.22)	↓	Normal Grade I	None	Marked fetal flexion No fetal movement	No molar changes

19.0	1.31 (1.11)	↓	Normal Grade I	None	Fetal movements present	No molar changes
N/A	N/A	↓	Normal Grade 0	None	Marked fetal flexion	Immature placenta (no molar changes)

ceral organ hypoplasia, or a relatively slower visceral mitotic rate may account for these findings.

Strikingly decreased amniotic fluid volume was present in all six viable gestations. Blackburn et al.[1] reported the occurrence of clinical polyhydramnios in 64% of triploid deliveries but noted that oligohydramnios was also more common. Oligohydramnios, when present, may reflect decreased renal blood flow as a consequence of the intrauterine growth retardation.

An absence of placental hydropic change was confirmed by pathologic examination in four of five placentas examined. Jacobs et al.[2] suggested that the development of trophoblastic hyperplasia in paternally derived triploidy contributes to uterine retention after early embryonic-fetal death. The late-aborting (nonaborting) triploids of maternal origin would be nonmolar. Unfortunately, chromosome polymorphism studies to identify the parental extrahaploid source were not performed. Nonetheless, the lack of hydropic or molar change in four of five placentas studied suggests a predominance of maternal origin.

It is concluded that the combination of early onset (generally ≤28 weeks) fetal growth retardation, extreme head-to-body disproportion, decreased amniotic fluid, and a lack of obvious placental molar change may be indicative of a triploid fetus. These sonographic features should prompt analysis of karyotype and appropriate obstetric intervention if triploidy is confirmed.

The finding of obvious molar change, regardless of fetal status, necessitates immediate analysis of karyotype and, if triploidy is present, expeditious delivery to avoid the development of potentially life-threatening toxemia.

Recurrent small for gestational age birth: Perinatal risks and outcomes

Honor M. Wolfe, M.D., Thomas L. Gross, M.D., and Robert J. Sokol, M.D.
Detroit, Michigan, and Cleveland, Ohio

The risk of recurrent small for gestational age birth, as well as maternal and fetal-neonatal characteristics associated with recurrence, was examined in 174 mothers of consecutively delivered small for gestational age infants followed through an additional 240 livebirths. There was a twofold and fourfold increase in the risk for small for gestational age birth after one and two small for gestational age births, respectively. Although an intervening average for gestational age birth decreased the risk of recurrence, these women remained at increased risk over the general population. Given the history of a previous small for gestational age birth, perinatal risks and outcomes considered individually would not improve the prediction of recurrence. However, the significantly higher frequency of these variables, considered as a group, among mothers with recurrent small for gestational age birth suggests an association with underlying maternal disease, for example, chronic hypertension, substance use and abuse, more severe fetal-neonatal compromise, and recurrent small for gestational age birth. Recurrent small for gestational age birth should initiate a search for persistent, underlying maternal disease. (AM J OBSTET GYNECOL 1987;157:288-93.)

Key words: Intrauterine growth retardation, recurrence, small for gestational age, perinatal risk

Intrauterine growth retardation represents a major source of perinatal morbidity and mortality. Clinical risk assessment remains an important adjunct to sonographic and biochemical methods for the diagnosis and management of impaired growth in utero.[1] Risk factors associated with an initial small for gestational birth have been well delineated.[2] However, of the more than 2000 articles published on intrauterine growth retardation in the obstetric and pediatric literature during the past 20 years, only a small number have addressed the issue of the birth of a small for gestational age infant as a risk for aberrant fetal growth in subsequent pregnancies, that is, risk of recurrence.[3-5] Although a history of a previous small for gestational age birth has been reported to be among the most predictive factors for subsequent intrauterine growth retardation,[3] some of the studies of recurrence have been limited because of sample size[4] and the number of factors examined.[5] Other problems, including the definition used for small for gestational age birth[3] and the growth curve used,[4] may limit the generalizability and comparability of previously reported results.

Our purpose in the present study was to test the hypothesis that the birth of a small for gestational age infant is a substantial risk for subsequent growth retardation. It was further hypothesized that certain perinatal risks and outcomes might increase the risk of recurrent small for gestational age births and thus be useful to identify those mothers of a small for gestational age infant in whom growth retardation will recur.

Material and methods

The 5738 consecutive, singleton livebirths occurring at Cleveland Metropolitan General Hospital from Jan. 1, 1977 through Dec. 31, 1978 were classified according to birth weight for gestational age into birth weight percentile categories with use of data collected prospectively and stored as part of a computer-based perinatal data base.[6] Gestational age was estimated from the Ballard modification of the Dubowitz examination,[7] and birth weight percentile was determined from the Cleveland growth curve. Records of women delivering a small for gestational age (less than the tenth birthweight percentile) infant (index small for gestational age birth) were reviewed. Mothers of an index small for gestational age birth with at least one additional livebirth recorded at that institution from Jan. 1, 1979 through Dec. 31, 1984 were designated as the study sample. Derivation of this study sample is illustrated in Fig. 1.

The study sample was divided, as indicated in Fig. 2, into two groups according to whether the first

recorded livebirth at the hospital after the index small for gestational age birth was small for gestational age (group I) or not small for gestational age (group II). All subsequent deliveries were similarly classified as small for gestational age or not small for gestational age. The risk for a recurrent small for gestational age birth after the index small for gestational age birth was calculated by determining the frequency of small for gestational age births in the first delivery after the index small for gestational age birth and dividing this by the total number in the study sample (group I divided by [group I + group II]). This value was then divided by the base rate for small for gestational age births observed in our general obstetric population to obtain an estimate of the relative risk.[8] The risk for the birth of an infant weighing less than the twenty-fifth percentile was calculated in a similar fashion by determining the frequency of infants with birth weights less than the twenty-fifth percentile[9] after the index small for gestational age birth and dividing by the base rate for this occurrence in our general population. Risk of recurrence after two consecutive small for gestational age infants was calculated according to the same base rate, as was the relative risk for the birth of a small for gestational age infant in women whose index small for gestational age birth was followed by the birth of an average for gestational age infant.

For patients in the study sample, maternal and neonatal records from the index small for gestational age birth and the next recorded livebirth were reviewed for 14 historical risk factors, nine maternal factors, and five fetal-neonatal factors. These had been chosen a priori as potential risks for recurrence and measures of fetal-neonatal compromise based on previously reported associations with an initial small for gestational age birth. Groups I and II were compared for the frequency of risk factors in the index small for gestational age birth and the next recorded livebirth to evaluate which, if any, risk factors in either pregnancy could be used to identify those mothers of small for gestational age infants who would again deliver a growth-retarded infant.

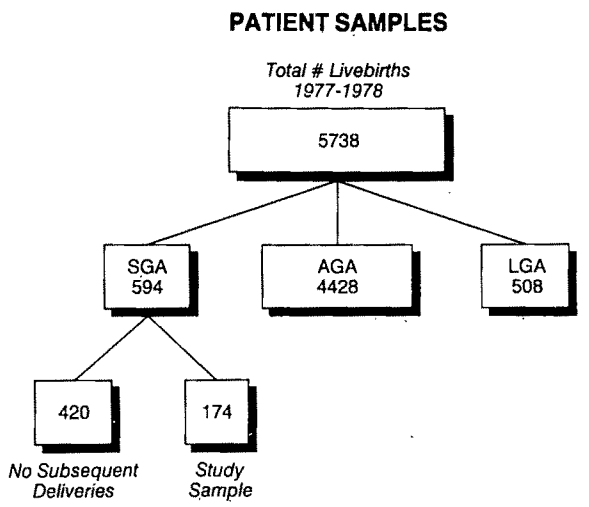

Fig. 1. Birth weight percentile for singleton, livebirths during 1977 and 1978 and derivation of the study sample. *SGA* = Small for gestational age; *AGA* = average for gestational age; *LGA* = large for gestational age.

Statistical analysis was by χ^2 for categoric variables and Student *t* test for continuous variables. Since the hypotheses were directional, one-tailed p values were calculated. To control at least in part for multiple comparisons, $p < 0.01$ was considered significant.

Results

Of the 5738 livebirths in 1977 and 1978, 594 (10.4%) were less than the tenth birth weight percentile, and 1434 (25%) were less than the twenty-fifth percentile. As shown in Fig. 1, of the 594 women with an index small for gestational age birth, 194 were delivered of at least one additional infant at the same institution during the study period. The study group consisted of 174 of these births for which complete perinatal records were available. As shown in Table I, the mothers in the study group were delivered of a total of 240 additional infants during the study period, with a range of one to five deliveries per patient. Comparison of maternal and infant characteristics showed that the study group was a highly representative subgroup of the 594 small for gestational age deliveries during 1977 and 1978 (Table II).

The birth weight percentile categories of infants born to the study group after the index small for gestational age birth are shown in Fig. 2. Fig. 3 summarizes the relative risk for the birth of an infant weighing less than the tenth and twenty-fifth percentile based on past obstetric history. Small for gestational age births recurred in 22.4% (39/174) (group I/group I + group II) of women in the study group after the index small for gestational age birth, resulting in a relative risk for the birth of a small for gestational age in-

fant of 2.2 times (22.4/10.4). This was significantly higher than that for the general population ($\chi^2 = 27.3$, $p < 0.001$). Among the study group mothers, 79% (137/174) were delivered of infants weighing less than the twenty-fifth percentile (relative risk, 3.2 times). The relative risk for a small for gestational age birth after two small for gestational age births (4.4 times) was also increased significantly over that for the general pop-

ulation ($\chi^2 = 14.5$, $p < 0.001$). The increased risk for a small for gestational age birth when the index small for gestational age birth was followed by an average for gestational age birth was less than that after one or two small for gestational age births but remained higher than that for the general population (2.0 times).

Comparisons between groups I and II for risks associated with the index small for gestational age birth are shown in Table III, and those that occurred in the first subsequent pregnancy are seen in Table IV. Few factors differentiated those mothers in whom growth retardation recurred from those without this problem. However, there was a trend toward an increased frequency of medical complications and substance use and abuse in the index small for gestational age birth among mothers with recurrent small for gestational age births. Statistical significance was reached on individual variables for tobacco only ($p < 0.001$). Similar trends were present in the first subsequent delivery, with mothers in group I showing significantly higher systolic blood pressures, a greater than sixfold increase in alcohol use, and a twofold increase in illicit drug use.

Five parameters of fetal-neonatal outcome (birth weight, fetal distress, need for intrapartum fetal scalp pH sampling, meconium, hypoglycemia, and polycythemia) were compared between groups I and II in the index small for gestational age birth. Differences in mean birth weight did not reach statistical significance. Infants born to mothers with recurrent small for gestational age births (group I) had a fivefold increase (10% versus 2%) in the need for intrapartum fetal scalp pH sampling, a 3.8-fold increase (15% versus 4%) in the frequency of fetal distress, a 3.3-fold increase (5% versus 1.5%) in the frequency of neonatal hypoglycemia, and a 1.5-fold increase (15% versus 10%) in the frequency of meconium. Polycythemia was more frequent (9% versus 7.5%) among infants in group II. Analysis by goodness of fit χ^2 for nine maternal factors (screening hematocrit, pulmonary disease, renal disease, screening blood pressure, alcohol use and abuse, tobacco use, drug abuse, preeclampsia, and a history of a previous stillbirth) and five fetal-neonatal factors (birth weight, fetal distress, polycythemia, hypoglycemia, and meconium) in the index small for gestational age birth hypothesized a priori to be associated with recurrence and revealed that 12 of 14 differences were in the expected direction, that is, the risks and adverse outcomes were associated with recurrent small for gestational age births ($\chi^2 = 7.14$, $p < 0.01$). In the first subsequent pregnancy, two of nine maternal differences were in the expected direction ($\chi^2 = 4.45$, $p < 0.04$). Fetal and neonatal characteristics were not compared in this pregnancy since the two groups had different birth weight classification (small for gestational age versus average for gestational age).

Based on the number of livebirths at the institution from 1979 through 1984 and the women in our study, we estimate that mothers of small for gestational age infants accounted for a minimum of 4% of the small for gestational age births in this population.

Comment

Our finding of a twofold and fourfold increase in small for gestational age birth after one and two pre-

vious small for gestational age infants(s), respectively, confirms the assertion that a history of a previous small for gestational age birth is an important risk for intrauterine growth retardation.[5] Given a history of a previous small for gestational age birth, individual perinatal risks and outcomes do not appear to enhance the predictability of recurrence. When considered as a group, however, our results suggest an association among underlying maternal disease, more severe perinatal compromise, and recurrent small for gestational age birth.

The present study has several strengths, including a homogeneous, single-center population, with the growth curve used derived from previously delivered infants from the same institution. It is also among the first large studies that addressed the use of multiple maternal and fetal-neonatal characteristics for the identification of the risk of small for gestational age recurrence. However, since our study did not include maternal heights, our ability to estimate the relative contribution of constitutional and environmental factors to birth weight percentile was limited.

Previous authors have examined risk factors associated with recurrence. Tejani[4] reported a recurrence rate of 28% in 28 mothers of small for gestational age infants followed through an additional 32 deliveries. She concluded that the likelihood of recurrence is higher in women with severe pregnancy-induced hypertension, chronic hypertension, or drug abuse. Visser et al.[10] confirmed this finding in patients with recurrent, early (<34 weeks) intrauterine growth retardation. Neither Visser et al. nor Tejani, however, performed statistical evaluation of their results, and selection bias may have been present. Nonetheless, the current results are in general agreement with their findings of a trend toward increased medical complications among mothers with recurrent small for gestational age births.

In their study of more than 1000 small for gestational age pregnancies, Patterson et al.[5] confirmed that a synergistic effect between hypertension and a history of a previous small for gestational age infant increased the risk of recurrent growth retardation. Our data, which examined additional medical complications, including renal disease, pulmonary disease, and alcohol use and abuse, are in agreement with their findings. Similar birth weight and gestational age in groups I and II in this study are not consistent with the conclusion of Patterson et al. that recurrence is related to the severity of intrauterine growth retardation, at least as reflected in birth weight percentile. Nonetheless, our data on additonal fetal-neonatal parameters lend support to the supposition that the risk for recurrent intrauterine growth retardation may be related to the severity of the underlying problem.

The large number of infants in this study whose birth weights were less than the twenty-fifth percentile after a small for gestational age birth suggests that fetal growth, although not meeting the criterion for a small for gestational age birth, continues to be suboptimal.

In conclusion, a history of a small for gestational age birth is a major risk for growth retardation. This study confirms a substantial recurrence rate and further estimates that a minimum of 4% of small for gestational age births are attributable to recurrence. Although it appears that growth retardation recurs more frequently among mothers with medical complications, all women with a history of a small for gestational age birth should be considered at increased risk in subsequent pregnancies. In addition, the presence of recurrent small for gestational age births should alert the clinician to the possibility of persistent underlying abnormalities such as renovascular disease and substance use and abuse that might not be apparent in the current pregnancy. Because preceding small for gestational age and preterm low birth weight pregnancies have different risks in the perinatal period, obstetric history and antenatal risk scoring should include not only birth weight but also gestational age and birth weight percentile.

Successful fetal therapy for cystic adenomatoid malformation associated with second-trimester hydrops

Steven L. Clark, M.D., Dennis J. Vitale, M.D., Stephen D. Minton, M.D., Ronald A. Stoddard, M.D., and Patty L. Sabey, R.N.
Provo, Utah

Fetal hydrops secondary to cystic adenomatoid malformation was detected in a second-trimester fetus. In utero thoracoamniotic shunt placement resulted in resolution of the hydrops. At term, there was no evidence of pulmonary hypoplasia. (AM J OBSTET GYNECOL 1987;157:294-5.)

Key words: Cystic adenomatoid formation, second trimester hydrops, fetal therapy

Cystic adenomatoid malformation is an uncommon congenital pulmonary anomaly that may result in fetal hydrops, pulmonary hypoplasia, and fetal or neonatal death.[1,2] When associated with early fetal hydrops, this condition has been considered to be uniformly fatal.[1] We present here the first reported case of successful in-utero treatment of cystic adenomatoid malformation associated with massive second trimester hydrops.

Case report

A 36-year-old woman, gravida 6, para 2, abortions 3, underwent ultrasonic examination to document gestational age, revealing a single viable fetus and biometric parameters consistent with 20 weeks' gestation. Real-time ultrasonographic examination revealed that the fetal thoracic cavity was occupied by a single cystic lesion measuring 10 by 6 by 6 cm (Fig. 1). The fetus was also noted to be grossly hydropic with massive ascites and edema of the scalp. Detailed fetal anatomic survey revealed no evidence of additional anatomic malformation. The thoracic lesion was felt to represent cystic adenomatoid malformation versus a remnant cyst of neurogenic or enteric origin. After approval by a multidisciplinary review panel, informed consent was obtained, and the fetus underwent simple transthoracic aspiration of the cyst and genetic amniocentesis. The cyst was completely emptied and when decompressed allowed documentation of normal intrathoracic and cardiac anatomy. Chemical analysis of the aspirated fluid revealed it to be serous.

After 48 hours the cyst was noted to be reexpanding, its dimensions measuring 6 by 8 by 6 cm, and intrathoracic shunting was performed. A 13 cm section of Fr. 6.5 polyethylene tubing was fashioned in a "double pigtail" pattern. The catheter was introduced over a 21 cm 18-gauge pencil-tip needle/stylette combination under local anesthetic, under direct and continuous ultrasound observation (General Electric RT 3000 real-time unit, 5 mHz linear transducer) into the posterior subscapular region of the right fetal chest and into the cyst. The needle was then withdrawn leaving the proximal coiled end extrathoracically within the amniotic cavity. Prompt and complete drainage of the cyst was observed. The fetus tolerated this procedure well. Throughout the next 17 weeks of gestation, the patient underwent weekly ultrasonography. Within 3 weeks of shunt placement evidence of ascites, pleural and pericardial effusions, and edema of the scalp had completely resolved, and fetal activity was noted to increase. At 37 weeks' gestation the patient underwent amniocentesis for documentation of fetal pulmonary maturity and primary cesarean section. A living female with Apgar scores of 8 and 9 and a weight of 2680 gm was delivered. The infant cried vigorously immediately after delivery, had normal blood gas values, and required neither ventilatory support nor supplemental oxygenation. At the time of delivery the extrathoracic portion of the shunt lumen appeared to be occluded with vernix; however, fluid was noted to be leaking from the fetal thoracic cavity around the shunt. The infant was taken to the operating room the same day (Fig. 2). A thoracotomy was performed and the distal end of the tube was found to lie within a cystic cavity contained within the right middle pulmonary lobe. The catheter was removed under direct surgical visualization, and the infant underwent resection of the right middle lobe. Both right upper and lower lobes were normal in size and consistency. They inflated readily intraoperatively and showed no clinical evidence of hypoplasia. Subsequent pathologic examination confirmed the diagnosis of macrocystic adenomatoid malformation. After surgery the infant did very well and remained on room air. At the time of this re-

port (age 14 months) the infant is showing normal growth and development without evidence of residual disease.

Comment

Fetal breathing and fluid exchange appear to be essential to normal pulmonary development; second trimester oligohydramnios may produce pulmonary hypoplasia at birth, regardless of cause.[2] Previous literature suggests that early cystic adenomatoid malformation associated with hydrops also results in insufficient pulmonary development to support life after birth and is uniformly fatal.[1] However, we have demonstrated that even with massive hydrops and extreme compression of pulmonary structures before 20 weeks' gestation, aggressive fetal surgical intervention may result in drainage of the cyst and resolution of the hydrops and allow normal pulmonary development. In addition to cystic adenomatoid malformation, conditions to be considered in the differential diagnosis of antenatally diagnosed fetal thoracic cystic masses include pulmonary sequestration, bronchiogenic and enteric cysts, and diaphragmatic hernia. Although cystic adenomatoid malformation may result in fetal or neonatal death, it is only rarely associated with other congenital anomalies. Associated fetal hydrops is felt to be the result of venacaval obstruction and cardiac compression from the extreme mediastinal shift caused by these lesions. Although it has been suggested that loss of protein from the lesion into the amniotic fluid may contribute to such hydrops, this did not appear to be the case in our patient because the fluid aspirated from the cyst was aproteinaceous.[1]

When cystic adenomatoid malformation is diagnosed antenatally, a team approach is imperative, involving a perinatologist who is skilled in real-time ultrasonography and direct ultrasound-guided intrauterine manipulation, as well as a neonatologist and pediatric surgeon. There can be no question that such an aggressive multidisciplinary approach to an anomalous fetus who classically would have been a candidate only for abortion resulted, in this case, in a normal, healthy infant. This procedure may be added to the slowly growing list of fetal surgical procedures that may now be performed on our patient, the fetus.

Labial agglutination secondary to a herpes simplex II infection

Bryan J. DeMarco, M.D., R. Scott Crandall, M.D., and Myroslaw M. Hreshchyshyn, M.D.
Buffalo, New York

A case is described of a young woman with labial agglutination secondary to a herpes simplex II infection that was successfully treated with laser vaporization. (AM J OBSTET GYNECOL 1987;157:296-7.)

Key words: Labial agglutination, herpes simplex II infection, laser vaporization

This report presents a case of labial agglutination. It is of interest because it is the first such case to be reported as a complication of a herpes simplex II infection.

Case report

A 35-year-old white nulligravid woman with normal monthly menses presented with occlusion of the introitus. She reported an outbreak of severe genital herpes simplex II infection 2½ years previously, which was confirmed by a viral culture. She described suffering from a high fever, arthralgias, and myalgias that were treated with oral analgesics during this attack. Shortly after this episode she noticed occlusion of the introitus, being unable to have intercourse or insert a tampon.

Examination of the external genitalia revealed agglutination of the labia minora in the midline with multiple small fenestrations present (Fig. 1). Anteriorly, the urethral meatus was visible. A single digit was inserted posteriorly to reveal a normal cervix and uterus.

The patient was treated surgically on an ambulatory basis with laser therapy. The adhesion band was vaporized with a Sharplan 1100 laser at a power density

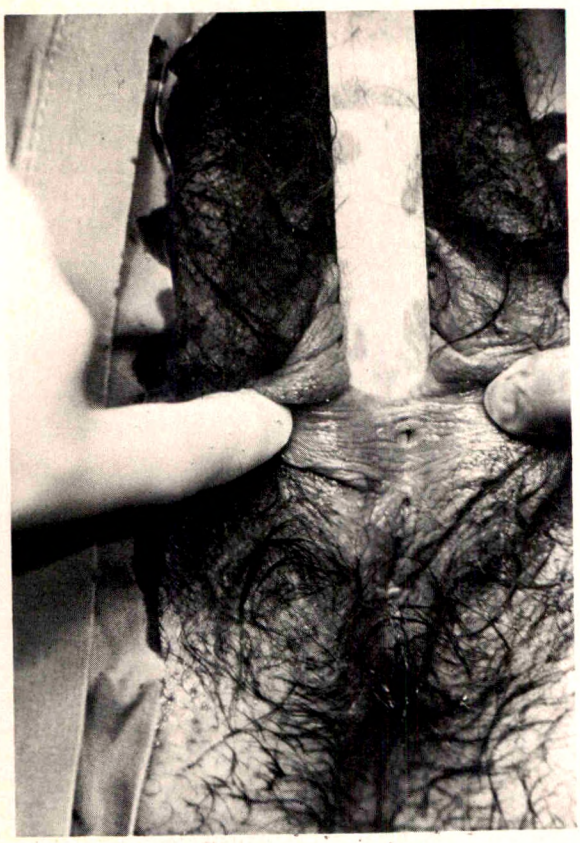

Fig. 1. Before laser therapy.

Fig. 2. After laser therapy.

of 469 W/cm² while she was under local anesthesia. Two wooden tongue depressors were placed behind the fused labia to protect the urethra and the adjacent vaginal mucosa. The labia were separated without difficulty with complete hemostasis. A gauze coated with petroleum jelly was then placed in the vaginal outlet to prevent adhesion reformation. Postoperative follow-up at 2, 6, and 8 weeks revealed no reformation of adhesions and a normal-appearing introitus (Fig. 2). The patient denied any further difficulty with intercourse.

Comment

Genital herpes has been known to predispose to many complications. There have been reported cases of urethral stricture, genital edema, and lymphatic suppuration. This is the first known, reported case of labial agglutination as a complication of genital herpes simplex II infection. Labial fusion has been previously reported in premenstrual girls and postmenopausal women. These are usually secondary to trauma, bacterial infections, or estrogen deficiency. The treatment of labial agglutination has been primarily estrogen administration for a 3- to 4-week period. This patient was treated successfully by laser vaporization while under local anesthesia.

Barriers to receiving adequate prenatal care

Marilyn L. Poland, Ph.D., R.N., Joel W. Ager, Ph.D., and Jane M. Olson, B.A.
Detroit, Michigan

One hundred eleven postpartum patients who received varying amounts of prenatal care (no care, inadequate care, intermediate care, and adequate care) were assessed for demographic, medical, and sociocultural factors by interview and review of the medical chart. Six sociocultural factors identified by stepwise multiple regression contributed to 49% of the variance for amount of prenatal care: amount of insurance, attitudes toward health professionals, delays in suspecting pregnancy, delay in telling others about the pregnancy, perception of the importance of prenatal care, and initial attitudes about being pregnant. Results are discussed in terms of developing outreach programs altered to the patient's needs and life-styles. (Am J Obstet Gynecol 1987;157:297-303.)

Key words: Prenatal care, barriers, outreach

Most (78%) women in this country begin prenatal care in the first trimester of pregnancy. However, 5% enter care in the third trimester or not at all.[1] The importance of receiving adequate prenatal care was highlighted recently by the U.S. Surgeon General, who set a national goal for at least 90% of pregnant women in each racial and ethnic group to begin prenatal care in the first trimester by 1990.[2]

Studies of natality statistics indicate that mothers who are single, black, under 18 years of age, and poor are most likely to receive little or no prenatal care.[3] Attitudinal surveys of women who receive inadequate prenatal care report that negative attitudes toward being pregnant, low perceived value of prenatal care, and structural barriers such as lack of insurance, transportation, and babysitters discourage prenatal visits.[4-8] Few studies examine the relative effects of demographic, medical, and attitudinal factors on amount of prenatal care received.

The following study was undertaken (1) to determine the relative effects of sociodemographic, medical, attitudinal, cultural, and structural variables on prenatal care seeking in low income, primarily black women who receive varying amounts of prenatal care and (2) to identify specific areas within the health care domain that might be altered to encourage women to receive adequate care.

Parity	Risk status (antenatal score)	Other structural barriers to prenatal care	
	Length of gestation	Time delay in telling others about pregnancy	Time delay (mos): suspected pregnancy to telling second person
		Initial attitude toward pregnancy	(1) Negative (wanted abortion), (2) mixed, (3) positive
		Amount of insurance	(1) No insurance, (2) on/off insurance, (3) insurance over entire pregnancy
		Importance of prenatal care	(1) Not important, (2) somewhat important (3) very important
		Attitude toward health professionals	(1) Negative (fear, hate, bad experiences), (2) mixed, (3) positive

who delivered at Hutzel Hospital in Detroit were studied 1 to 5 days postpartum. The women were all English speaking, had been delivered of viable infants, and agreed voluntarily to participate. The research protocol was approved by the Institutional Review Board. The sample consisted of women who were listed as "walk-ins" (did not have a physician associated with the hospital) and those who received prenatal care in the hospital's antenatal clinic. The sample was collected over an 18-month period, and we attempted to interview the same number of walk-ins and clinic patients in any given week.

Data collection and scoring. Data collection consisted of a structured interview with open-ended and fixed-choice questions and review of the mother's medical chart. The interview explored experiences, attitudes, beliefs, values, and health-seeking behaviors from the time the woman thought she might be pregnant through delivery. The subject's early recollections of her pregnancy included how (symptoms) and when she first knew she was pregnant, how she felt about the pregnancy, who she told and when, and descriptions of the reactions and advice she received. Prenatal care-seeking activities included a list of all providers, times of initial visits, locations, reasons for visits, total number of visits, cost, problems obtaining care, and an assessment of value and benefit. Subjects were also asked to list important items physicians could do for them, the importance of seeing a doctor, how they obtained information about pregnancy, and describe experiences with labor and delivery.

Responses to open-ended questions were recorded in the subject's own words and then analyzed by content analysis and converted into ordinal scales. Content analysis consists of the placement of items, responses, or behaviors into predefined categories.[9] For example, amount of insurance was coded as "no insurance" if the subject had no insurance over the pregnancy period, "part insurance" if she had insurance over part of the pregnancy, and "total insurance" if she was covered throughout pregnancy. A scale from 1 to 3 represented these categories. Reliability of these scales was assessed by comparing scores of two coders who scored responses independently. Scaled responses with agreement less than 0.90 by rank order correlation were deleted from the analysis. Table I lists the major variables analyzed and organized into three categories: background variables, medical variables, and sociocultural variables. Variables derived by content analysis are also shown.

Medical chart review included obtaining sociodemographic information and selected maternal and antenatal conditions that were reliably assessed for each patient. These conditions included maternal age greater than 35 years or less than 16 years, parity greater than 5, diabetes mellitus, hypertension, heart disease, hematocrit less than 27% at delivery, drug abuse, gestation greater than 42 weeks, sexually transmitted disease, and isoimmunization. Items were given unit weights and totaled to yield a risk score.

Statistical analysis. The basic analytic problem was the identification of factors (variables) that distinguish among women receiving varying amounts of prenatal care. Amount of prenatal care was determined by the month of gestation that care began, number of appointments, and length of gestation. Kessner et al.[10] proposed a formula that accounts for these factors using the standards of the American College of Obstetricians and Gynecologists for number of prenatal care visits and yielded three levels of care: adequate, in-

Table II. Differences among groups on background and medical variables (analysis of variance)

Comparison	Groups				$p <$
	Adequate (n = 35)	*Intermediate (n = 35)*	*Inadequate (n = 19)*	*No care (n = 22)*	
Age	24.5	21.6	24.5	25.2	NS
Race—black (%)	84.6	88.2	88.6	87.2	NS

Parity	1.2	1.0	2.1	1.7	0.05
Antenatal risk score	0.54	0.35	0.90	0.86	0.05
No. of prenatal providers	1.51	1.22	1.25	0	NS

termediate, and inadequate care. We modified this procedure to give us four levels of prenatal care: adequate (n = 35), intermediate (n = 35), inadequate (n = 19), and no care (n = 22). For example, a woman who registered in the first trimester, kept 7 monthly appointments, and delivered at 32 weeks received adequate prenatal care; a woman who registered in the sixth month, kept 7 appointments, and delivered at term received an intermediate amount of care. Women who had a prgnancy test only were placed in the no care group. For analyses requiring dichotomized groups, amount of prenatal care was categorized into appropriate care (adequate/intermediate) and poor care (inadequate/no care) groups.

The analysis was conducted in several steps. First, frequency distributions and descriptive statistics including intercorrelations were obtained for all variables within each care group. Second, variables were compared across the four care groups by one-way analysis of variance, intercorrelation, and χ^2 analyses. Variables for which complete data were available and for which there was a pattern of differences across the four groups were retained for further analysis. Third, the selected independent (predictor) variables, and the background and medical variables of age, parity, and total risk score, were entered into a stepwise multiple regression analysis to identify variables predictive of women who received varying amounts of prenatal care. In this analysis, we considered the four care groups to be equally spaced on the continuum of prenatal care.

Fourth, we entered the significant predictor variables identified by multiple regression into a stepwise, linear discriminant, function analysis using the dichotomized care groups (appropriate versus poor) as the dependent variable. In addition to identifying the significant discriminating predictors, this analysis also allowed us to determine how well these patients could be classified into the two groups on the basis of the significant predictor variables.

Fifth, using the set of significant predictors from the linear discriminant, function analysis, evaluation of risk of receiving poor care as a function of the number of "risk" factors for the woman was obtained by means of a logistic regression analysis. For this analysis, we dichotomized the predictor variables into "at risk" versus "no risk" categories. The "at risk" categories for each variable were: (1) insurance (scores 2 and 3), (2) month gestation pregnancy was suspected (2 or more months), (3) attitudes toward health professionals (scores 2 and 3), (4) initial attitude toward pregnancy (scores 2 and 3), (5) time delay in telling others (1 or more months), (6) perceived importance of prenatal care (scores 2 and 3).

Results

Comparisons among the four care groups on selected variables were made by one-way analysis of variance. Results for background and medical variables are shown in Table II.

Background and medical variables. There were no significant differences in race, age, number of prenatal providers, and marital status, although the trend was that those receiving better care were more apt to be married. All 21 adolescents less than 19 years of age received some prenatal care, although 15 registered in the second trimester. Almost 40% (35/89) of women who received any prenatal care went to more than one provider. Most (64%) prenatal care was provided by an obstetrician or family physician in a clinic or private office. However, 36% of the women made between one and 16 visits to emergency walk-in centers located throughout Detroit. These centers were popular because they were convenient (most women walked to them), no appointment was necessary (some women had no phone), and they were inexpensive (most took Medicaid or they charged an average $10/visit). On the negative side, the physicians were felt to be less competent, they provided no pregnancy literature, and no return appointments were given.

There were significant differences among groups for parity with better care received by those with lower parity. This corroborated statements made by many women across groups that prenatal care was most important for a first pregnancy, whereas women who had

Importance of prenatal care	0.69	0.48	7.82
Delay in telling others of pregnancy	0.70	0.49	4.03

*Variables are listed in order of entry. The variables of age, parity, maternal risk, and substance abuse failed to attain significance.

a baby felt that they already knew how to take care of themselves and needed less care. There were also significant differences among groups in the antenatal risk score. Women in the inadequate and no care groups had higher risk scores; the differences were primarily because of one factor—use of illicit drugs. Almost 31% (13/42) of women in the poor care group abused drugs, primarily heroin, compared with 7% of women in the adequate care group.

Sociocultural variables. Differences among the four groups on six sociocultural variables and the principal means of transportation for the three groups receiving care are seen in Table III. Of these seven variables, five showed significant differences in the expected directions among the groups. In all five instances, the major differences were between the higher two (appropriate care) and lower two (poor care) groups. The sixth variable, month of gestation the woman suspected she might be pregnant, was significant when the four groups were dichotomized into appropriate versus poor groups.

The largest difference among the groups was amount of insurance; the no care group had much less insurance than the other three groups. All but three women in the sample who had insurance had Medicaid; 12 had no insurance. Interestingly, only three of these 12 patients had sought Medicaid insurance, and two were told they were ineligible. The others were Medicaid eligible but did not pursue insurance for a variety of reasons, primarily related to lack of motivation and the difficulties of applying.

Although there were no significant differences among the three groups who received prenatal care on the major source of transportation used, there was a linear trend, with women receiving the most care who used the most expensive modes of transportation such as a car or a taxi, whereas women who received less care were more likely to use public transportation or walk. All women who used public transportation complained about unreliable bus schedules, poor weather, and dangerous conditions. There were also no differences among groups for early signs of pregnancy or problems seeking care such as need for a babysitter, long wait to see a doctor, or seeing different doctors. Most women across groups complained about these problems.

Table IV lists the six significant predictors from the multiple regression analysis in order of entry. Amount of insurance was the best predictor of amount of prenatal care as evaluated by the F to remove, followed by initial attitude toward pregnancy and the month in which the pregnancy was suspected. Attitudes toward health professionals and importance of prenatal care were also strong predictors. One other variable, time delay in telling others about the pregnancy, was also marginally significant. The multiple correlation for the six predictors was 0.70, accounting for about one half

Table V. Discriminant function analysis with two prenatal care groups as criterion (poor care versus appropriate care) (n = 110)*

Group	*Correct classification (%)*	*No. cases predicted*		
		Poor care	*Appropriate care*	*Totals*
No. of cases observed				
Poor care	83	33	7	40
Appropriate care	84	11	59	70
Totals	84	44	66	110

*These are jackknifed values.

Table VI. Logistic regression analysis predicting probability of receiving poor care as a function of "risk" score (n = 110)

Risk score	*No. of cases in poor care group*	*No. of cases in adequate care group*	*Observed proportion receiving poor care*	*Predicted proportion receiving poor care*
6	1	0	1.00	0.98
5	5	0	1.00	0.93
4	7	2	0.78	0.79
3	17	17	0.50	0.53
2	7	20	0.26	0.25
1	3	23	0.12	0.09
0	0	8	0.00	0.03
Total	40	70		

of the variance of amount of care. We note that the six predictors were relatively uncorrelated, with the highest correlation of −0.26 between attitudes toward health professionals and month that pregnancy was suspected.

Table V shows the jackknifed classification results from the linear discriminant, function analysis based on the six significant predictors. The overall percentage of correct classification was 84%. Sensitivity was 83%, with 33 of 44 poor care patients correctly identified. Specificity was similar (84%), with 59 of 70 of the appropriate care group correctly classified. The false-positive and false-negative rates were 11% (seven of 66) and 25% (11 of 44), respectively.

As a final analysis, we evaluated the prediction of poor care from an "at risk" score derived from the six predictor variables as previously described. The composite score for "risk" of receiving poor care ranged from 0 to 6. Table VI shows the probability or receiving poor care as a function of amount of "risk." The predicted probabilities from the model ranged from 0.98 for a risk score of 6 down to 0.03 for a risk score of 0.

Comment

The purpose of this study was to examine the relative effects of demographic, medical, and sociocultural factors on amount of prenatal care received. The key finding is that six sociocultural factors that were consistently related to amount of prenatal care were identified: amount of insurance, attitude toward health professionals, delay in suspecting pregnancy, delay in telling others about the pregnancy, perception of the importance of prenatal care, and initial attitudes about the pregnancy, which together predicted about one half of the variance for amount of prenatal care.

Before further discussion of the results, three caveats must be made. The most important concerns the issue of causality in a correlational design. We do not claim that the six variables found to predict level of care are necessarily causative. Although lack of insurance might certainly be a reason for not seeking care, it might also reflect a more pervasive attitudinal problem concerning the care for oneself. Similar comments can be made about variables of perceived importance of prenatal care and attitudes toward health professionals. The question of the causal status of the predictors is, of course, critical for both gaining a better understanding of care-seeking behaviors and designing interventions and policies that will improve the amount of care sought and received. To explore possible causal models involving these variables, we intend to conduct path analyses on a larger and more heterogeneous sample currently being collected.

A second caveat concerns the retrospective nature of the data collection. The nature of the sample, particularly the target walk-in group, imposes this constraint.

Women who receive no prenatal care are unavailable for study in an antenatal clinic.

The third caveat concerns the generalizability of the results. The present sample represented a fairly homogenous group of women who were generally poor, primarily black, and for the most part lived in inner city Detroit.

Despite these caveats, our findings indicate similarities and differences between women receiving appropriate amounts of prenatal care and those receiving poor care. They were similar in age, race, marital status, number of prenatal providers they used, major sources of transportation to prenatal care, their need for babysitters, and problems with providers, such as long waiting times and seeing different physicians. The fact that we found no differences in race or marital status could be from the homogeneity of the sample. Although there were no significant differences in age, women receiving intermediate amounts of care were slightly younger than the other three groups. This was in large part, due to adolescents who delayed telling their parents they were pregnant and who subsequently entered care in the second trimester. The similarities in the number of prenatal providers among the groups who received care reflected the growing popularity of emergency walk-in centers as a source of prenatal care for this population. Although most women who used them subsequently transferred to other providers, some received all their prenatal care there. One hypertensive mother of six kept her appointments at a perinatal center when she felt well but visited the emergency walk-in center when she did not feel well enough to take the bus and wait for long periods to see the perinatologist. The fact that there were no differences in complaints about public transportation, waiting times, and seeing different doctors indicates that this is a common problem across groups. It may be that women who have little motivation to seek prenatal care would view any problem, such as transportation, as a major barrier.

There were, however, significant differences among groups. Six factors reflecting a broad array of social supports and personal attitudes predicted about one half of the variance in amount of prenatal care received.

Social support. The two care groups differed significantly in the tangible assistance and emotional support they received during pregnancy. For example, women who received poor care had less insurance partly because they perceived great difficulty in registering for Medicaid. This included confusion over the long forms they were required to read and fill out and negative attitudes from social service workers who advised them about public assistance. The isolation they felt from social service workers extended to health care professionals, who were perceived by many women as frightening, hostile, and uncommunicative. Some women who were initially undecided about their pregnancy delayed seeking care until the second or third trimester only to encounter professionals who chastised them for registering late. The lack of emotional support and assistance was also apparent in their families and friends. Women in the poor care group delayed telling others about their pregnancy because they anticipated a negative response or they felt they had no one to tell who would be interested. They were more often without a telephone and had fewer people available who would help them with tangible factors such as transportation to prenatal care.

Women who received appropriate amounts of prenatal care found friends, family, and professionals who were supportive. These women were more often transported to prenatal care by a friend or member of their family, and they received continuous advice and emotional support throughout their pregnancies.

Personal attitudes. Women who received little or no prenatal care had more negative attitudes about being pregnant (many initially wanted an abortion), the importance of prenatal care, and health professionals. They saw a physician intermittently to be "checked" or when they did not feel well. Others felt they already knew how to care for themselves from a previous pregnancy. Some believed that as long as the fetus moved, they felt alright, and they took vitamins, routine prenatal care was unnecessary. Many had had bad experiences with physicians and nurses with a previous pregnancy or felt that prenatal care was boring.

The appropriate care group had more positive attitudes about their pregnancies, and they felt that prenatal care was important to ensure a healthy baby and mother. Although some complained about discourteous service, discontinuity of care, and long waiting times, they thought that the physicians were generally competent and concerned about their welfare. Although some encountered problems receiving prenatal care, they found ways to overcome them or discounted them as inconveniences that poor persons should expect.

These findings have important clinical implications. Our system of prenatal care is based on the premise that it is an important service designed to monitor and manage the progress of pregnancy and that all pregnant women will seek prenatal care as their maternal responsibility as long as it is available. However, although prenatal care services for the poor may be available, they may be relatively inaccessible to them because of a lack of support, reliance on public transportation systems, location of clinics for the poor, differences in values and attitudes about prenatal care among some

poor women, problems associated with reading and understanding information, fear of doctors, discontinuity of care, and discourteous service.

There are two possible approaches to improve access: change the attitudes and values of women who do not seek adequate care or alter the provision of prenatal services. The latter approach is probably more feasible, since we know more about altering health services and less about how to change attitudes. In addition, by changing service delivery to meet the identified needs of patients, our understanding of their social environment and life-styles, along with concern for their health, is communicated to them. This process may be our most effective way of altering their attitudes toward seeking prenatal care.

Toward this goal, the following steps are proposed. First, experiences and attitudes of pregnant women receiving varying amounts of prenatal care should be assessed locally. This could be done as individual interviews or as focus group discussions. Second, the information derived from the women should be used (1) to identify structural barriers within the health delivery system that can be altered, (2) to identify factors that reflect personal barriers or "social risk" for not receiving prenatal care, and (3) to develop population-specific outreach efforts for "at risk" women.

This marketing approach to providing prenatal care services to the poor could assume a variety of different forms. For example, in Detroit efforts are underway to reach women who are "at risk" for not receiving adequate prenatal care through a 24-hour telephone information and referral service, community baby showers, training of welfare mothers to act as paraprofessional outreach workers, and a variety of collaborative efforts among health and social agencies (including emergency walk-in centers) designed to simplify, coordinate, and augment services to pregnant women and infants. We are using the predictor variables from this study as an indicator of social risk status to identify pregnant women who are in the greatest need of support services. Finally, interviews with new mothers are continuing to increase the size and heterogeneity of the sample to assess the relative effects of the predictor variables on birth weight.

In summary, technologic advances in prenatal care have placed the United States in the forefront of the early identification and management of maternal-fetal abnormalities. However, some women who could benefit the most from these procedures receive little or no prenatal care for some of the reasons previously listed.

Unless measures are taken to improve access, women who cannot or will not traverse the maze of people, places, and information necessary to obtain prenatal care will continue to enter our hospitals as walk-ins. Those who obtain health care may not benefit from the most appropriate obstetric care if women at high medical risk select the convenience of walk-in centers over perinatal centers or if they receive less care with a subsequent pregnancy because our manner of providing prenatal care fails to communicate its importance.

We acknowledge Drs. Robert Sokol and Paul Giblin for critical reviews of earlier drafts of this paper and the late Krystal Brown for her sensitive interviews of postpartum mothers and devotion to this project.

Red blood cell zinc protoporphyrin testing for iron-deficiency anemia in pregnancy

Ron B. Schifman, M.D., James E. Thomasson, M.D., and James M. Evers, M.D.
Tucson, Arizona

The diagnostic value of ferritin, transferrin saturation, and red blood cell zinc protoporphyrin for detecting iron depletion and predicting third-trimester anemia was studied in 87 women attending a private obstetrics clinic. A decline in ferritin and transferrin saturation and an increase in red blood cell zinc protoporphyrin levels were observed in third-trimester measurements when compared with those of the first trimester. Third-trimester anemia (hemoglobin <11.5 gm/dl or 115 gm/L) was detected in 13 (15%) women. Red blood cell zinc protoporphyrin was the only test that consistently demonstrated significantly different mean values between anemic and normal subgroups. The diagnostic sensitivity and predictive value of red blood cell zinc protoporphyrin for evaluating iron depletion and risk of anemia in pregnancy compared favorably to those of ferritin and transferrin saturation measurements. The operational simplicity and low cost of red blood cell zinc protoporphyrin measurements are additional characteristics that favor this procedure for office testing. (AM J OBSTET GYNECOL 1987;157:304-7.)

Key words: Iron-deficiency anemia, protoporphyrin, pregnancy

Iron deficiency, produced by increased physiologic requirements, is the most common cause of anemia in pregnancy.[1] Iron stores can be effectively monitored with serum ferritin or transferrin saturation measurements[2] and anemia may be prevented by oral iron supplementation.[3] Red blood cell zinc protoporphyrin measurements are also capable of identifying patients with depleted iron stores,[4] although little information is available about the diagnostic value of this test in obstetric practice.

Zinc protoporphyrin accumulates in red blood cells when heme biosynthesis is disturbed by decreased iron availability.[4] Measurement of the red blood cell zinc protoporphyrin concentration therefore provides information about both storage iron and its use.[5] Furthermore, this test is analytically more suitable than serum ferritin or transferrin saturation measurements for office testing because red blood cell zinc protoporphyrin can be quickly and inexpensively assayed from a drop of whole blood by hematofluorometry.[6] Red blood cell zinc protoporphyrin testing has been successfully used to screen children, blood donors, and other groups for iron depletion.[6-8] This study evaluated the diagnostic value of red blood cell zinc protoporphyrin testing for assessing iron stores and anemia risk in patients attending a private obstetrics clinic.

Material and methods

Eighty-seven women attending a private obstetrics clinic were studied after providing informed consent to participate. This study was approved by the Human Subjects Committee of the Arizona Health Sciences Center and Tucson Medical Center. All women received standard care and completed term pregnancies. In addition, all were prescribed oral iron supplements (ferrous fumarate, 45 mg/day) as part of a multivitamin-mineral complex.

Venous blood samples were collected from study participants at each trimester period. Hemoglobin measurements were performed by the Coulter method. The precision (coefficient of variation) of this method is 0.6% at the level of 13.0 gm/dl (130 gm/L). Serum ferritin determinations were performed by radioimmunoassay (Leeco Diagnostic, Deerfield, Michigan), with a precision (coefficient of variation) of 7% at 35 ng/ml (35 μg/L). Ferritin values <12 ng/ml (12 μg/L) were interpreted as abnormal.

Transferrin saturation was calculated as the percentage of serum iron versus total iron binding capacity and was measured by coulometry and ion-exchange methods (ESA Ferochem 3050, Bedford, Massachusetts). This method has a precision (coefficient of variation) of 5% at the level of 100 mg/dl (17.91 μmol/L).

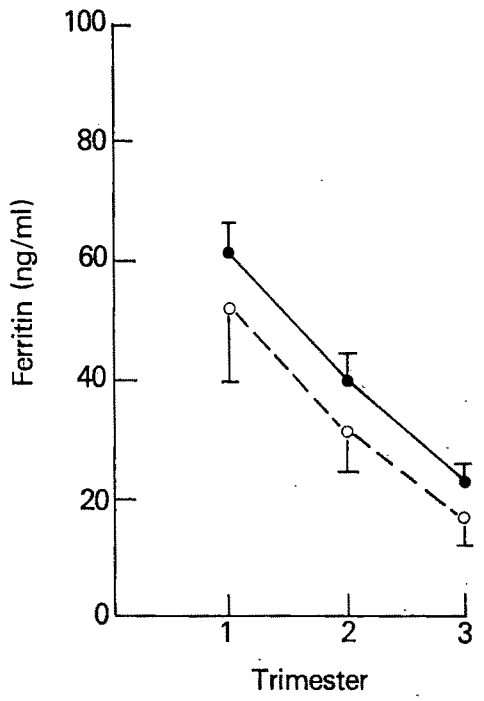

Fig. 1. Changes in ferritin during pregnancy in women developing anemia in the third trimester (○) and in women without anemia (●). Results given as mean and SEM.

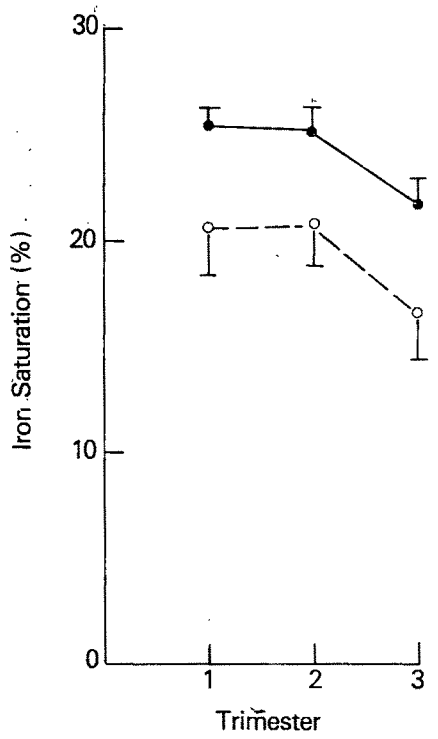

Fig. 2. Changes in iron saturation during pregnancy in women developing anemia in the third trimester (○) and in women without anemia (●). Results given as mean and SEM.

Transferrin saturation levels below 16% were interpreted as abnormal.

Red blood cell zinc protoporphyrin was measured by hematofluorometry on washed cells as previously described.[9] The hematofluorometer is a dedicated front surface fluorometer that directly measures the red blood cell zinc protoporphyrin:hemoglobin ratio as a function of the intensity of light emitted by zinc protoporphyrin fluorescing at 594 nm versus the amount of excitation light absorbed by hemoglobin at 420 nm. This method has a precision of 4% at the level of 80 μg/dl red blood cells (14.33 μmol/L red blood cells). A value of ≥60 μg/dl red blood cells (10.75 μmol/L red blood cells) was interpreted as abnormal.

All tests were performed by experienced medical technologists. The accuracy and precision of all methods were monitored with appropriate controls and external proficiency testing (College of American Pathologists and Centers for Disease Control). The Student *t* test (two tail) was used to test for statistical differences between means, and Bayes' theorem was used to calculate the sensitivity and predictive value of test results.[10] Sensitivity is defined as the percentage of true positive results to true positive plus false negative results. Predictive value of a positive (abnormal) test result is the percentage of true positive results to true positive plus false positive results.

Table I. Evaluation of test results for predicting third-trimester anemia (hemoglobin ≤ 11.5 gm/dl or 115 gm/dl)

	Trimester		
Test	*1*	*2*	*3*
Sensitivity (%)			
Red blood cell zinc protoporphyrin	38	54	62
Ferritin	23	23	54
Iron saturation	31	23	46
Predictive value of positive (abnormal) test			
Red blood cell zinc protoporphyrin	56	50	35
Ferritin	27	25	32
Iron saturation	33	15	24

Results

Thirteen (15%) of 87 women demonstrated hemoglobin concentrations equal to or below 11.5 gm/dl (115 gm/L) and seven (8%) had values below 11.0 gm/dl (110 gm/L) at the third-trimester testing period. These groups were compared with the remaining study population to evaluate the value of ferritin, transferrin saturation, and red blood cell zinc protoporphyrin for predicting third-trimester anemia (Table I). Prevalence of iron depletion (%)*	22	30	46
Predictive value of negative (normal) red blood cell zinc protoporphyrin result (%)†	86	82	77
Predictive value of positive (abnormal) red blood cell zinc protoporphyrin result (%)†	44	57	70

*Interpretive criteria: Depleted iron stores defined as ferritin ≤ 12 ng/ml (12 µg/L) or iron saturation ≤ 16%.

†Abnormal red blood cell zinc protoporphyrin test defined as ≥60 µg/dl of red blood cells (10.75 µmol/L).

shows the predictive value of normal and abnormal red blood cell zinc protoporphyrin test results for assessing iron stores.

Figs. 1 through 4 show test results at each test period for the two subgroups with third-trimester hemoglobin levels above or below 11.5 gm/dl (115 gm/L). A progressive decline in ferritin concentrations was observed throughout pregnancy. However, no significant difference in mean values between anemic (n = 13) and normal (n = 74) groups was seen in the first, second, and third trimesters (t = 0.47, t = 0.84, t = 1.43, respectively; $p > 0.05$). Mean transferrin saturation results demonstrated a significant difference between subgroups only during the third trimester (t = 2.00, $p < 0.05$), while mean red blood cell zinc protoporphyrin concentrations in the anemic and normal groups were significantly different in the first (t = 3.56, $p < 0.001$), second (t = 2.78, $p < 0.01$) and third (t = 4.53, $p < 0.001$) trimesters.

Comment

The results of this study confirm previous observations that show a steady downward trend in ferritin concentrations during the first and second trimesters of pregnancy.[3] However, a further decline in iron stores, observed during the third trimester, was not expected since iron supplementation was provided to all study participants.[2, 3] This outcome may have been caused by poor compliance with prescribed iron supplements,[12] insufficient dosage of supplemental iron,[3] or impaired absorption.[13] Nevertheless, these results indicate that periodic assessment for iron-deficiency anemia is warranted during pregnancy, even in women given standard doses of iron supplements.

Third-trimester anemia was considered a harmful consequence of iron depletion and was used as an end point to assess the relative diagnostic efficiency of ferritin, transferrin saturation, and red blood cell zinc pro-

toporphyrin tests. The incidence of iron depletion steadily increased from 22% to 46% between the first and third trimesters, although only 13 (15%) women were found to have hemoglobin concentrations at or below 11.5 gm/dl (115 gm/L) during the third trimester. Holly[14] and Romslo et al.[15] observed that red blood cell protoporphyrin concentrations rose primarily during the third trimester of pregnancy in women who did not receive iron supplementation. Our study group demonstrated a gradual increase in red blood cell zinc protoporphyrin levels throughout pregnancy, with the highest levels and most marked changes observed in the third trimester in those who had anemia. This difference was not observed with ferritin or transferrin saturation results. Red blood cell zinc protoporphyrin measurements compared favorably with ferritin and transferrin saturation testing, when judged on the basis of diagnostic efficiency (that is, sensitivity and predictive value).

Iron absorption increases during pregnancy as a compensatory response to expanded utilization, and this serves to maintain normal hematopoiesis in the presence of depleted iron stores.[1] However, some women with deficient iron stores are unable to maintain adequate red blood cell mass by increasing iron absorption, and anemia may develop when apparently normal iron reserves are used ineffectively. This may explain why red blood cell zinc protoporphyrin, as a physiologic measure of iron utilization, was more effective than other tests for predicting anemia. An abnormal red blood cell zinc protoporphyrin result signifies a decompensated state of iron deficiency with ineffective heme synthesis[5] and may provide the best single choice of tests for assessing iron requirements and risk of anemia in pregnancy.

The red blood cell zinc protoporphyrin test has potential application for office testing. However, the results of this study may represent the best performance that can be achieved with the hematofluorometer, since measurements were performed on washed venous blood samples, by an experienced medical technologist. In the office laboratory, red blood cell zinc protoporphyrin will probably be measured directly from whole blood capillary samples by less skilled operators. Whole blood measurements may produce higher values because of interference by plasma constituents, and this has the potential to increase the frequency of falsely abnormal test results.[9] In addition, inaccurate results may occur from calibration failures if assay performance is not carefully monitored by appropriate control materials.[16] In spite of these potential difficulties, the hematofluorometer red blood cell zinc protoporphyrin assay has been shown to be an effective "field" method in iron-depletion screening programs.[6,7] It will be necessary to verify that reliable method performance and diagnostic effectiveness can also be maintained under typical office laboratory conditions. At the present time, the red blood cell zinc protoporphyrin test should be considered as a cost-effective alternative to other laboratory methods for identifying iron depletion and evaluating the potential for anemia in pregnancy.

The normal parturient's admission temperature

David B. Acker, M.D., Erica B. Schulman, M.A., Bernard J. Ransil, M.D., Benjamin P. Sachs, M.B., B.S., D.P.H., and Emanuel A. Friedman, M.D., Sc.D.
Boston, Massachusetts

The relationship between oral temperature taken at the time of admission and the duration of elapsed labor was evaluated. Onset of labor data revealed a diurnal distribution with an apogee at midnight to 2 AM and a nadir at 11 AM to noon. Temperature data ranged from 94.3° to 99.7° F (34.6° to 37.6° C). The mean temperature of 97.8° ± 0.8° F (36.6° ± 0.44° C) is significantly lower ($p < 0.001$) than the clinical reference temperature of 98.6° F (37.0° C). A likely explanation is the coincidental admission time (early to late morning) and the nadir of the diurnal variation in temperature. Linear regression fitted to the data (after deletion of six hypothermic outliers) yielded the relationship: temperature = 97.8° F + 0.0115 × duration of elapsed labor (temperature = 36.6° C + 0.0064 × duration of elapsed labor) for which the correlation coefficient is not statistically significant. (AM J OBSTET GYNECOL 1987;157:308-11.)

Key words: Febrile morbidity, labor, normal parturient, temperature

Fever is a sign of considerable clinical significance. It is generally defined in medicine as an elevation of body temperature above normal daily variation. Although frequently associated with infection, it may be associated with other conditions or states, including dehydration or prolonged exertion. Difficult or long labors are said to be associated with an increase (rarely above 100.4° F or 38.0° C) in the core temperature.[1,2]

A parturient's moderately elevated or slightly rising temperature presents the clinician with a diagnostic dilemma. The ability to distinguish between an early infectious process and a variation in the elevation of normal intrapartum temperature has obvious practical importance. Recent obstetric publications have not provided guidelines for interpreting this common finding.[3-5]

The purpose of this article is to provide a reliable measure of the admission temperature of a group of normal parturients and to determine the variation, if any, of temperature with respect to the duration of labor, thereby providing data to help define both the limits of normal temperature and the level at which fever can be said to exist and warrant investigation and care.

Material and methods

All patients and their singleton babies delivered at Beth Israel Hospital during the calendar year 1982, numbering 2746 pairs, were available for study. Data were abstracted from the patients' charts, collated, edited, verified, and stored on computer tapes by specially trained staff. The data base consisted of demographic and medical characteristics, obstetric complications, labor and delivery events, and neonatal outcome.

From this population, a subset was selected that fulfilled, on retrospective chart review, the following criteria: the gestational age was 37 to 41 weeks (dating from the last menstrual period); the onset of labor was spontaneous; the membranes were intact (specifically, there was no history of ruptured membranes, no evidence of amniotic fluid was noted in the vagina during the physical examination on admission, and there was subsequent documentation of either spontaneous or artificial rupture of membranes); the gravida delivered spontaneously; and there was no evidence of any antepartum, intrapartum, or postpartum infection or inflammatory disease. In all 502 patients satisfied all criteria and served as the sample population for this study.

The patient's statement concerning the onset of regular uterine contractions, as documented in the admission history, was taken as the time of onset of labor. The parturient's time of admission and concomitant vital signs, which included an oral temperature obtained with an IVAC temperature measuring system (IVAC Corp., San Diego, Calif., accuracy ± 0.2° F or 0.11° C) were recorded by the primary nurse. The difference between the two recorded times was used to define the duration of elapsed labor for the purposes of this investigation. Although additional temperature

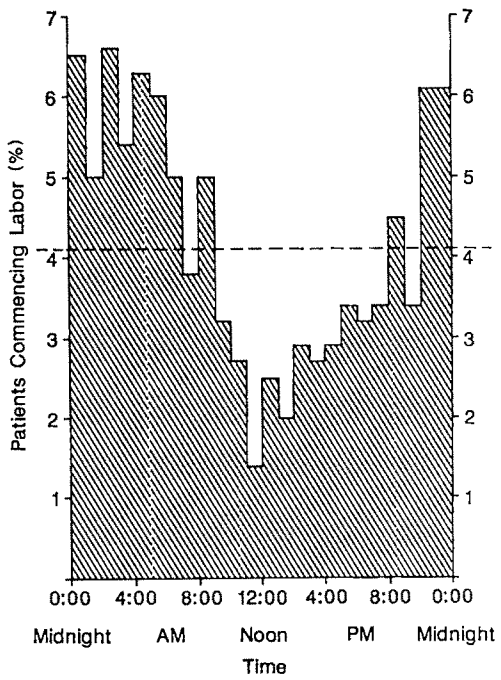

Fig. 1. Relationship between incidence of perceived initiation of spontaneous labor in the presence of intact membranes and time of day. The *dashed line* at 4.2% represents the percentage of patients who would perceive the beginning of labor if it occurred randomly.

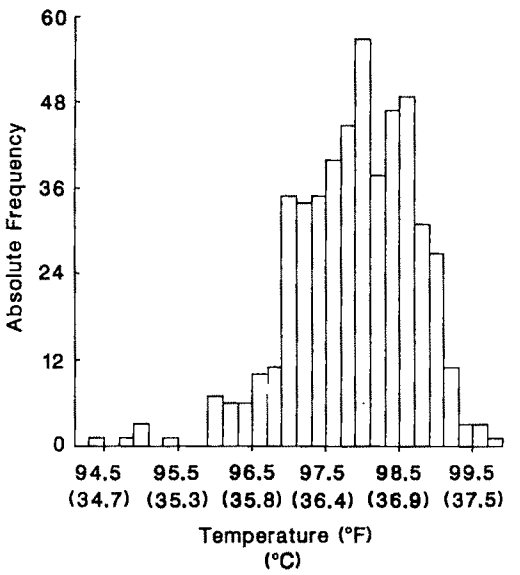

Fig. 2. Histogram (nonnormal) displays parturients' oral temperature at the time of admission to the hospital.

readings were made periodically over the course of the labor, usually at 4-hour intervals, only the first recording was used in this study.

The onset of labor, temperature on admission, and duration of elapsed labor data were evaluated for the distribution properties by means of D'Agostino's statistic, histograms, skewness (degree of asymmetry), and kurtosis (degree of peakedness) and plotted to evaluate the relationship, if any, between temperature and duration of elapsed labor. The resulting observed linear relationship was evaluated by linear least squares regression.

Results

The relationship between the percentage of gravidas perceiving the onset of regular contractions and the time of day of that perception is displayed in Fig. 1. A definite diurnal distribution is evident with an apogee between midnight to 2 AM and a nadir between 11 AM to noon.

The temperature readings obtained on admission are displayed in Fig. 2. The range for the 502 normal gravidas was 94.3° to 99.7° F (34.6° to 37.6° C). The average temperature was 97.8° ± 0.8° F (36.6° ± 0.44° C) (mean ± SD). These data were not normally distributed by D'Agostino's statistic ($p < 0.01$). A histogram showed both significant kurtosis ($p < 0.01$) and significant negative skewness ($p < 0.01$).

The duration of elapsed labor data exhibited a Poisson distribution, with a range of 0.25 to 32 hours (Fig. 3). More than half (56.4%) of the patients were admitted within 5 hours of the onset of labor. The nonnormal character of the distribution is further illustrated by the low median value, 4.25 hours, compared with an arithmetic mean of 5.89 hours, and the large coefficient of variation (84%). Distribution typing established that the duration of elapsed labor data were log normal in character with a geometric mean of 4.31 hours.

To evaluate the relationship between temperature and the duration of elapsed labor, a correlation scatterplot (Fig. 4) was made, which yielded a wedge-shaped distribution about a temperature of 97.8° F (36.6° C). A linear regression fitted to the data yielded the relationship: temperature = 97.8° + 0.0148 × duration of elapsed labor (temperature = 36.6° C + 0.0082 × duration of elapsed labor). The correlation ($r = 0.09$) and linear behavior were statistically significant at the $p = 0.04$ level.

Comment

The onset of labor data of these 502 normal parturients reveal a diurnal distribution rhythmicity that has previously been noted by Kaiser and Halberg[6] and by Shettles.[7] For a disproportionate number of patients and for reasons that remain unexplained, the initiation or the perception of the initiation of spontaneous labor

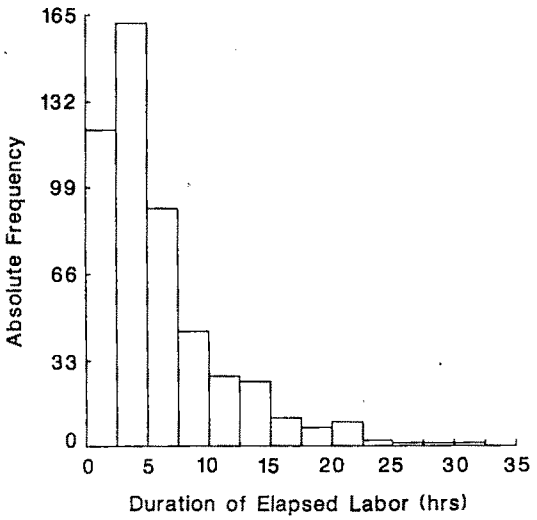

Fig. 3. Histogram displays the duration of elapsed labor at the time of admissison to the hospital.

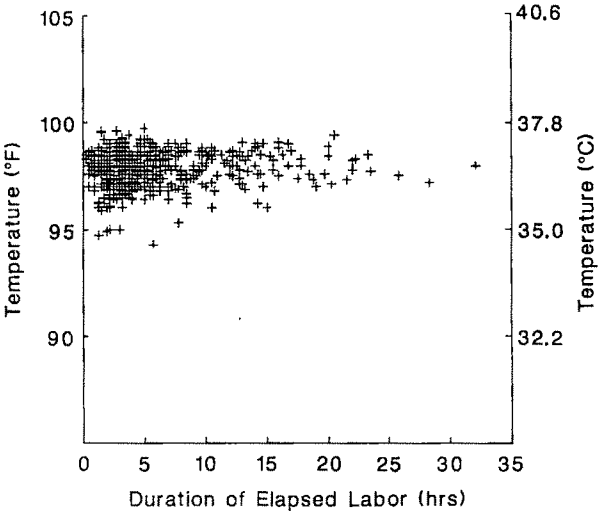

Fig. 4. Scatterplot relates the temperature at the time of admission of 502 normal parturients to the duration of elapsed labor. Note the six cases at the extreme low end of the temperature scale.

(in the presence of intact membranes) occurs during periods of rest or asleep.

The temperature data exhibit two interesting features. First, the mean temperature of 97.8° ± 0.8° F (36.6° ± 0.44° C) is significantly lower ($p < 0.001$) than the clinical reference temperature of 98.6° F (37.0° C); indeed, 79% of the patients have a temperature less than 98.6° F (37.0° C). Furthermore, the temperature distribution is skewed significantly toward lower temperatures.

The elapsed duration of labor data offers a clue to a likely explanation. Most of the patients experienced the onset of regular contractions in the very late evening or early morning hours. The median time from the onset of labor to admission was 4.25 hours. Therefore it is likely that most of the patients were admitted (and had their temperature taken) during just that period of the morning when the diurnal variation of temperature in pregnancy was at its nadir.[8]

However, several other factors might account for the findings: the accuracy of the measuring system (varies ±0.2° F or 0.11° C), an error in the clinical use of the digital thermometer, an error in the acceptance of the clinical norm of 98.6° F or 37.0° C (obtained in the days when mercury thermometers were the standard measurement device), or a bias toward hypothermia in this sample population (as suggested by the negative skewness in the histogram).

However, the inaccuracy of ±0.2° F (0.11° C) does not explain a difference of four times that value.

The digital thermometer may not be properly standardized or used, or it may detect temperature correctly, or the older mercury thermometers consistently were overread. Alternatively, both measurement devices could be in error and contribute to the relatively small difference of 0.8° F (0.44° C). These are important technologic issues that the design of this study does not address.

Turning to the remaining factor, the possibility of bias, we note that the histogram of this population (Fig. 2) shows a small group of six patients at the extreme low end of the temperature scale. The mean of this small subgroup, 94.9° ± 0.3° F (34.9° ± 0.17° C), lies 3.6 SD below the total sample mean and differs significantly from it in both mean ($p < 0.001$) and variance ($p < 0.001$). We consider the possibility that these cases represent a hypothermic subpopulation and that the parent distribution is bimodal and nonhomogeneous.

Acting on this assumption and deleting these six possible outliers yields a sample population of 496 gravidas that is normally distributed by D'Agostino's statistic and does not differ significantly in mean ± SD from the unedited sample (97.9° ± 0.7° F versus 97.8° ± 0.8° F) (36.6° ± 0.39° C versus 36.6° ± 0.44° C). Skewness ($p = 0.02$) and kurtosis ($p = 0.05$) are still statistically significant (but borderline). The range of temperatures decreases from 5.4° to 3.8° F (3.0° to 2.1° C).

A correlation scatterplot of the edited distributions (not shown) yields a linear regression of the form: temperature = 97.8° F + 0.0115 × duration of elapsed labor (temperature = 36.6° C + 0.0064 × duration of elapsed labor) for which the correlation coefficient ($r = 0.076$) is not statistically significant.

Therefore the outcome of analysis is a sample distribution of 496 individual gravidas who were admitted

with a mean temperature of 97.9° ± 0.7° F (95% confidence limits ± 0.07%) or 36.6° ± 0.39° C (95% confidence limits ± 0.04%) after a mean (arithmetic) duration of elapsed labor of 5.9 ± 5.0 hours (95% confidence limits ± 0.4%). The more precise (but less clinically familiar) geometric mean duration of elapsed labor was 4.31 hours (almost identical to the median). Therefore these cases may be regarded as a reference population from which the following clinical inferences may be drawn.

The diurnal variation in the onset of labor and a gravida's normal temperature is well established but not frequently emphasized clinical concepts. The clinician should be alert to the significance of the time of day of a gravida's admission and the resulting admission temperature.

An admission temperature of 99.4° F (37.4° C), which represents the mean + 2 SD, in a normal parturient with intact membranes is uncommon (especially in the morning hours). It can be expected to occur, with use of a one-tail value, on the basis of our distribution, once in 50 cases. Values of 100.2° F (37.9° C), which represent the mean + 3 SD, should not occur but once in 1000. The reasonableness of these frequencies can be tested against the current data base. Six of 496 patients have a temperature >99.4° F (37.4° C) whereas 10 are expected due to chance. There are no patients whose temperature exceeds 99.7° F (37.6° C), whereas two are expected due to chance.

Therefore in the absence of a history of ruptured membranes, a temperature elevation ≥99.4° F (37.4° C) may be indication of an abnormality such as unsuspected leakage of amniotic fluid (although not found in this series). A careful examination to confirm the presence of intact membranes should be initiated. This should include at the least visualization of the vaginal vault and fornices for amniotic fluid and the performance of a fern or Nitrazine paper test on suspected secretions. An ultrasonographic evaluation of amniotic fluid volume should be considered. Whether the membranes have ruptured, other sources of inflammation or infection should be considered. If the cause for the temperature elevation cannot be found, prudent management should include close observation and a well monitored in-hospital labor. Regardless of the duration of labor at the time of admission, the parturient should not be sent home.

Presently, the difference between the lower temperatures observed in this study and the more conventionally accepted reference temperature (98.6° F or 37.0° C) and the lack of any observed relationship between duration of elapsed labor and the admission temperature should not be taken to be in disagreement with the classic clinical teaching. Previous works related prolonged or difficult labors (inevitably associated with ruptured membranes and multiple pelvic examinations) to a slight rise in temperature. Our results are applicable only for the clinical conditions specified within this study. It would be inappropriate to generalize these data to other situations.

The data needed for correct interpretation of temperature in association with other than intact membranes are not available; a suitably designed prospective study is needed.

We thank Dr. Irwin H. Kaiser for his review of this manuscript and wise suggestions for its improvement. Data analysis was performed with the Core Laboratory Computer facilities.

Age-related changes in the female hormonal environment during reproductive life

Victoria C. Musey, M.D., Delwood C. Collins, Ph.D., Paul I. Musey, Ph.D., D. Martino-Saltzman, M.S., and John R. K. Preedy, M.D.

Atlanta and Decatur, Georgia

Previous studies have indicated that serum levels of follicle-stimulating hormone rise with age during the female reproductive life, but the effect on other hormones is not clear. We studied the effects of age, independent of pregnancy, by comparing serum hormone levels in two groups of nulliparous, premenopausal women aged 18 to 23 and 29 to 40 years. We found that increased age during reproductive life is accompanied by a significant rise in both basal and stimulated serum follicle-stimulating hormone levels. This was accompanied by an increase in the serum level of estradiol-17β and the urine levels of estradiol-17β and 17β-estradiol-17-glucosiduronate. The serum level of estrone sulfate decreased with age. Serum and urine levels of other estrogens were unchanged. The basal and stimulated levels of luteinizing hormone were also unchanged. There was a significant decrease in basal and stimulated serum prolactin levels. Serum levels of dehydroepiandrosterone and dehydroepiandrosterone sulfate decreased with age, but serum testosterone was unchanged. It is concluded that significant age-related changes in the female hormonal environment occur during the reproductive years. (Am J Obstet Gynecol 1987;157:312-7.)

Key words: Aging and hormones, estrogens, androgens, gonadotropins, prolactin

Although much information is available regarding the changes in the female hormonal environment at menarche and menopause, age-related hormonal changes during the intervening years have not been extensively investigated. Previous studies in regularly menstruating women have suggested that serum follicle-stimulating hormone (FSH) levels rise with increasing age, whereas luteinizing hormone (LH) levels remain unchanged.[1-3] However, apart from the gonadotropins, the effects of age on other hormones, including estrogens, during reproductive life are not clear.

Investigation in this area is complicated by our previous findings[4,5] that a first pregnancy causes long-term changes in the hormonal environment. Thus the effects of age and pregnancy must be separately determined. Previous studies[1-3] did not control for parity. To determine the effects of age during reproductive life, independent of pregnancy, we studied two groups of nulliparous women, a younger group aged 18 to 23 years and an older group aged 29 to 40 years. The following hormones were measured: basal and stimulated serum levels of prolactin, FSH, and LH; serum levels of estrone (E_1), estradiol-17β (E_2), estriol (E_3), and E_1 sulfate; urinary levels of total E_1, E_2 and E_3, together with their glucosiduronates were measured. The serum levels of the androgens testosterone, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEAS) were also measured.

Methods

Subjects. Thirty-five normal healthy female volunteers aged 18 to 23 years and 29 normal healthy female volunteers aged 29 to 40 years were recruited by a mass media campaign and studied after informed consent was obtained. The mean age in years ± SD was 20.4 ± 1.33 for the younger aged group and 33.9 ± 3.03 for the older aged group. All subjects were nulliparous, had a history of regular menstrual cycles, and had never taken oral contraceptives or other hormones. None were on medication at the time of the study. After medical histories were obtained and physical examinations were performed, the subjects with conditions known to be associated with abnormal hormone levels or others that would affect the study's outcome were excluded.

Experimental protocol. All subjects were studied during the early follicular phase (days 2-4) of the menstrual cycle. On day 2, each subject collected a 24-hour

urine sample. On day 3, a blood sample was collected, and a gonadotropin-releasing hormone (GnRH) stimulation test was performed. On day 4, a perphenazine-prolactin stimulation test was done (see below). Both stimulation tests were started between 8 and 9 AM after the subjects fasted overnight. All serum and urine samples were stored at −80° C until analyzed.

GnRH stimulation test. A 19-gauge butterfly needle was inserted into a forearm vein to facilitate blood collection. The needle was kept open with a heparin-saline solution. Baseline blood samples were collected for LH and FSH assays. A 100 μg bolus of GnRH was then given intravenously. Thereafter, blood samples were collected at 30-minute intervals for 90 minutes for LH and FSH assays. Serum was separated and stored as described above.

Perphenazine-prolactin stimulation test.[6] After insertion of a 19-gauge butterfly needle into a forearm vein, a baseline blood sample was collected for prolactin determination. Perphenazine (8 mg) was then administered orally, and further blood samples were collected at 3, 4, and 5 hours after the perphenazine administration to measure prolactin levels. The serum was separated and stored as above.

Procedures for hormone assays

Analysis of LH, FSH, and prolactin. Serum levels of LH, FSH, and prolactin were measured by radioimmunoassay (RIA) with commercial kits obtained from Serono Diagnostics, Inc., Braintree, Massachusetts. The reagents for measuring serum prolactin were obtained from Hybritech, San Diego, California. The intra-assay and interassay coefficients of variation established in our laboratory were LH, 2.8% and 4.4%; FSH, 3.1% and 7.7%; prolactin, 2.8% and 6.2%.

Analysis of estrogens. Serum levels of E_1, E_2, and E_3 were measured by RIA after ether extraction as previously described.[7] The intra-assay and interassay coefficients of variation for each estrogen were E_1, 6.8% and 11.2%; E_2, 5.4% and 8.2%; E_3, 6.1% and 9.1%. The E_1 sulfate level in serum was determined by direct RIA without previous hydrolysis after ether extraction to remove the free estrogens.[8] The intra-assay and interassay coefficients of variations were 6.4% and 9.5%, respectively. Urinary levels of the estrogen conjugates, E_1 glucosiduronate, E_2 17-glucosiduronate, and E_3-16α-glucosiduronate were determined by specific RIA as previously developed in our laboratory.[9] The intra-assay and interassay coefficients of variation for each compound were E_1 glucosiduronate, 6.9% and 10.8%; E_2 17-glucosiduronate, 6.5% and 10.2%; E_3 16α-glucosiduronate, 6.6% and 11.0%. The levels of E_1, E_2, and E_3 in urine were determined after hydrolysis with β-glucuronidase (*Helix pomatia*, type H-3, Sigma Diagnostics, St. Louis, Missouri). The free estrogen was extracted with ether and measured by specific RIA for the particular estrogen as previously described.[7] The coefficients of variation were the same as those of the free estrogens in serum.

Analysis of androgens. Serum levels of testosterone were measured by RIA after ether extraction as previously described.[10] The intra-assay and interassay coefficients of variation were 4.9% and 7.9%, respectively. Serum levels of DHEA were measured by RIA after ether extraction and LH-20 chromatography as previously described.[11] The intra-assay and interassay coefficients of variation were 6.4% and 10.1%, respectively. Serum levels of DHEAS were measured by RIA with a specific antiserum as previously described.[12] The intra-assay and interassay coefficients of variation were 5.4% and 8.2%, respectively. All the measurements for each hormone were done in a single assay.

Statistical analysis. Height and weight between younger and older aged groups were compared with the use of the *t* test for differences between means. A one-way analysis of variance was used to compare basal levels of the protein hormones (FSH, LH, prolactin) and the steroid hormones between younger and older aged subject groups.

A two-way repeated measures analysis of variance was used to compare stimulated levels for FSH, LH, and prolactin between groups, with main effects "younger, older" as the "between factor" and "time" (i.e., time of sampling) as the "within" or repeated measures factor.

The square root or log transformation was used to stabilize heterogeneous variances where appropriate. Subjects with missing data on the variable of interest were omitted from the analysis. Values outside the mean ± 2 SD were considered to be outliers and were also omitted. A value for $p \leq 0.05$ was taken to indicate statistical significance. Standard errors are given for descriptive purposes but are not used in the significance tests.

Results

Subjects. The mean height in inches ± SD for the younger aged group was 65.0 ± 2.39 and for the older aged group was 65.4 ± 2.31. There was no significant difference between the two means. The mean body weight expressed as percent of ideal body weight ± SD was 106.9 ± 15.6 for the younger aged group and 112.0 ± 11.4 for the older aged group. The mean body weights were not significantly different between the two groups.

Protein hormones. The basal serum FSH level was significantly higher ($p < 0.01$) in the older aged group than in the younger aged group (Table I). The mean values for stimulated FSH (Fig. 1) were also significantly higher in the older aged group ($p < 0.05$). There was no significant difference between the groups in

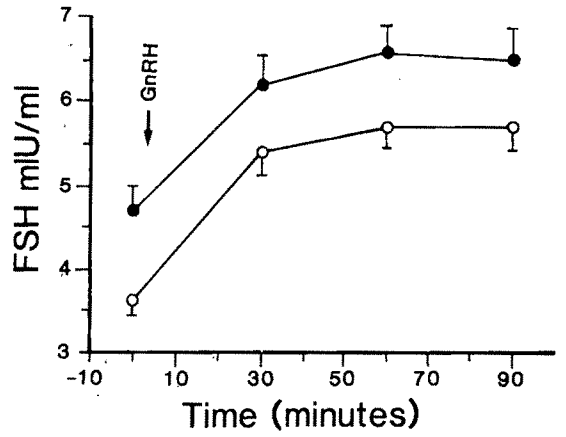

Fig. 1. Basal (time zero) and stimulated (30, 60, 90 minutes) levels of serum FSH after the intravenous administration of GnRH (100 μg) to subjects in the younger *(open circles)* and older *(closed circles)* aged groups. Both basal and stimulated values in the older aged group were significantly higher than in the younger aged group ($p < 0.01$).

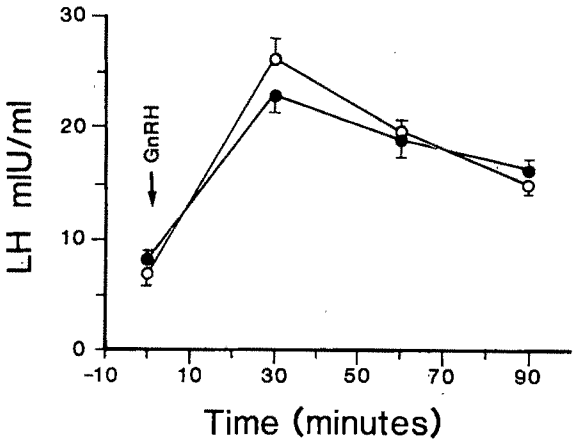

Fig. 2. Basal (time zero) and stimulated (30, 60, 90 minutes) levels of serum LH after the intravenous administration of GnRH (100 μg) to subjects in the younger *(open circles)* and older *(closed circles)* aged groups. There was no significant difference between the two groups.

either the basal serum LH or in stimulated serum LH values (Fig. 2). There was a significant ($p < 0.01$) decrease in the basal serum prolactin level in the older aged group. The stimulated prolactin values (Fig. 3) were also significantly lower ($p < 0.01$) in the older aged group.

Estrogens. The mean serum levels of E_2, E_1 sulfate, E_1, and E_3 for both groups are shown in Table II. The serum E_2 level was significantly higher ($p < 0.01$) in the older aged group, but the serum level of E_1 sulfate was significantly lower ($p < 0.01$). The serum E_1 level was lower in the older aged group, but the difference between the groups was not statistically significant. Serum E_3 levels were similar in both groups.

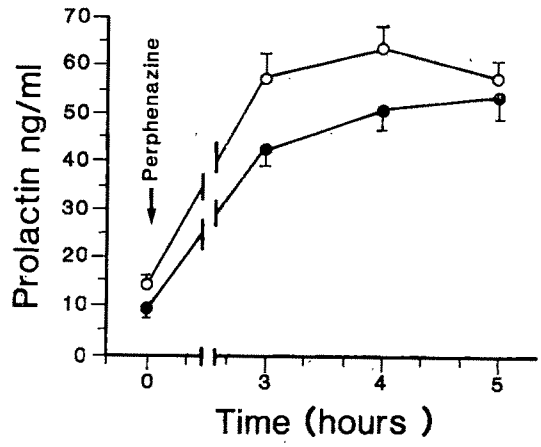

Fig. 3. Basal (time zero) and stimulated (3, 4, 5 hours) levels of serum prolactin after the oral administration of 8 mg perphenazine to subjects in the younger *(open circles)* and in the older *(closed circles)* aged groups. Both basal and stimulated values in the older aged group were significantly lower than in the younger aged group ($p < 0.01$).

The mean levels of E_2, E_1, E_3, and E_2 17-glucosiduronate in urine are shown in Table III. There were significant differences in urine levels of E_2 and E_2 17-glucosiduronate between the groups, with the older aged group having higher levels than the younger aged group. There was no significant difference between the groups in levels of E_1, E_3, E_1 glucosiduronate, and E_3 16α-glucosiduronate in urine.

Androgens. Mean serum levels of testosterone, DHEA, and DHEAS are shown in Table IV. There was no significant difference between the groups for serum testosterone. However, serum DHEA and DHEAS levels were significantly lower ($p < 0.01$) in the older aged group.

Comment

This study was designed to demonstrate the effects of age on the hormonal environment in women of reproductive age. Apart from cyclic alterations of the menstrual cycle, a first pregnancy induces long-term changes in the hormonal environment.[4, 5] Thus the effects of age and pregnancy must be separately determined. In this study we have excluded effects of pregnancy that would confound the issue by using nulliparous subjects only.

A second confounding variable is differences in serum hormone levels caused by circadian rhythm and/or episodic or pulsatile secretion. Such variation could complicate the interpretation of serum hormone values from single blood samples. In this study the time

Table I. Mean basal serum levels of FSH, LH, and prolactin in the younger and the older aged groups of nulliparous women

	Younger women (aged 18-23 yr)	*Older women (aged 29-40 yr)*	*Difference*	*p*

of day at which samples were collected was controlled by obtaining all samples for basal hormone measurements in the morning (between 8 and 9 AM), thereby minimizing the effects of circadian changes. In addition, the GnRH and perphenazine stimulation tests that were used are independent of pulsatile secretion and circadian changes.

A third variable that could impact on the hormonal environment is body weight. However, this variable was discounted by finding no significant difference between the two groups of women.

Previous studies of the effects of age on serum FSH and LH levels have dealt with only basal levels. Our results in relation to basal FSH and LH levels are consistent with those reports[1-3] that suggest a significant increase in basal FSH but no change in LH. However, by using only nulliparous women in this study, we have shown that pregnancy could not have been a factor in these effects.

The GnRH stimulation test used in this study also offers additional information about age-related changes, namely, an estimate of the pituitary secretory capacity of FSH and LH. We found an increased response of FSH to GnRH stimulation. No significant change in the response of LH to GnRH stimulation was seen in the older aged group. Therefore our results suggest that both basal serum levels and pituitary secretory capacity for FSH are affected by the aging process, whereas those of LH are not affected. The mechanism for the divergent basal levels and the response

of FSH and LH is not known but might be explained by feedback regulation of gonadotropin secretion by estrogens and/or inhibin. In this study the concomitant rise in serum levels of both FSH and E_2 argues against feedback regulation by estradiol as being responsible for the increase in FSH. Conversely, inhibin preferentially inhibits FSH secretion. Therefore decreased feedback inhibition of FSH secretion by ovarian inhibin could explain the selective rise in the FSH level.

A most interesting finding in this study was the significant age-related increase in the serum level of E_2. The increase in E_2 occurred in both the serum and urine and is consistent with one previous report.[13] The increased serum E_2 level may be caused by either increased ovarian secretion or decreased metabolism of E_2, which is metabolized principally through hepatic conjugation and E_1 formation. In this study the urine levels of both total E_2 and E_2 17-glucosiduronate were increased, whereas serum levels of E_1 sulfate and E_1 were decreased, suggesting that decreased metabolism through the E_1 pathway may account for the increased levels of E_2. However, an increase in ovarian secretion of E_2 remains a possibility that cannot be excluded with our results.

This age-related increase in serum E_2 levels in nulliparous women has important implications as a risk factor for breast cancer. It is well known that nulliparity increases the risk of breast cancer.[14, 15] Bernstein et al.[16] have recently reported that nulliparous women have higher serum levels of E_2 than parous women, indicating that previous pregnancy lowers serum levels of E_2. One possible mechanism for lowering serum E_2 levels in parous women is through the prevention of the age-related rise in the serum levels of E_2, which occurs in nulliparous women. An early first pregnancy could then reduce serum E_2 levels at an earlier age than a

late first pregnancy. This is consistent with the established finding that an early first pregnancy protects against breast cancer, whereas a late first pregnancy does not.[14, 15]

A decrease in basal serum prolactin levels with increasing age has been reported in the female subject, but postmenopausal women were included, and the long-term effects of pregnancy were not taken into account.[17-19] Yu et al.[13] found no significant change in basal serum prolactin levels with age in nulliparous women. Our results clearly indicate that there is an age-related decrease in both the basal levels of prolactin and the response of prolactin to perphenazine during the reproductive years.

We have previously reported that a first pregnancy induces long-term reduction in the secretion of prolactin.[4] In this study the effects of pregnancy were excluded by using only nulliparous women. Thus both the aging process and previous pregnancy affect prolactin secretion. However, serum prolactin levels are higher in nulliparous women than in parous women,[4, 13] indicating that a pregnancy at an early age will lower serum prolactin levels at an earlier age and for a longer period than the aging process.

There was again a divergence with regard to the androgens. There was no age-related change in serum levels of testosterone, whereas serum levels of both DHEA and DHEAS decreased. Serum DHEA and DHEAS levels decrease during pregnancy.[20] We have shown that the reduction in DHEA and DHEAS levels induced by a first pregnancy persists for several years.[5] The effects of age and pregnancy are frequently concurrent and difficult to separate. However, the effects of pregnancy were discounted in this study by using only nulliparous women. Our results clearly show that serum levels of DHEA and DHEAS change in response to age, as well as to a first pregnancy.

In summary, our studies indicate that increasing age during reproductive life in the woman is accompanied by a significant change in the hormonal environment that is independent of previous pregnancy. There is an increase in both basal serum FSH levels and the response of FSH to GnRH stimulation. In turn, this is associated with an increase in serum levels of E_2, urinary levels of total E_2 and E_2 17-glucosiduronate, and a decrease in serum levels of E_1 sulfate. Other serum and urinary estrogen levels are unchanged. Basal and GnRH stimulated levels of LH are also unchanged. Serum levels of DHEAS and DHEA decrease markedly, but testosterone remains unchanged. Both basal and perphenazine-stimulated serum levels of prolactin are markedly reduced. These changes in the hormonal milieu during the reproductive years have important implications about physiologic and pathologic conditions that are affected by reproductive hormones.

Evidence that estrogen may be a key factor in hyperprolactinemic anovulation: A case report

Hideki Sakamoto, M.D., Konbai Den, M.D., Yasumasa Kondo, M.D., Katsuo Tsubata, M.D., and Shigeo Takagi, M.D.

Tokyo, Japan

Although anovulation associated with hyperprolactinemia is not an uncommon cause of infertility, the precise mechanism of the pathogenic process that induces hyperactivity (hypertrophy with hyperplasia) of pituitary lactotropes is unknown. We have recently experienced a case of anovulation and hyperprolactinemia in a woman with ergot alkaloid intolerance in whom ovulation was restored by tamoxifen citrate administration. Since tamoxifen citrate administration also suppressed prolactin levels, it was suggested that a low but sustained serum level of estradiol and consequently continuous estrogenic stimulation may be an important causative factor in the development of hyperprolactinemic anovulation. (AM J OBSTET GYNECOL 1987;157:318-9.)

Key words: Estrogen, hyperprolactinemia, tamoxifen citrate

We present here a case of hyperprolactinemia associated with infertility. Ovulation was restored in this patient with a regimen of tamoxifen citrate administration.

Case report

A 24-year-old nulligravid housewife was referred to our clinic on September 20, 1986, because of amenorrhea of 2 months' duration. She had a negative urinary human chorionic gonadotropin test and withdrew to progesterone challenge at another clinic. The serum luteinizing hormone, follicle-stimulating hormone, and estradiol levels were 26 mIU/ml, 8.5 mIU/ml, and 57.4 pg/ml, respectively. There was a moderate rise of the serum prolactin level to 110 ng/ml (upper limit of prolactin in our clinic is 30 ng/ml) and normal thyroid-stimulating hormone levels of 1.3 uU/ml.

A series of sellar x-ray studies was negative. A course of bromocriptine (5 mg/day) was initiated on September 25 but was discontinued on that day because she developed marked nausea, vomiting, and epigastrial cramps after receiving 2.5 mg of the medication. At her second visit, an antiestrogen regimen with tamoxifen citrate (20 mg/day) was started.

On the thirteenth day of the regimen, the basal body temperature rose with increased cervical mucus production. Serum estradiol, progesterone, and prolactin levels were 440 pg/ml, 0.9 ng/ml, and 78.5 ng/ml, respectively, and the tamoxifen citrate regimen was stopped on the fourteenth day (Fig. 1). The basal body temperature remained high and progesterone and prolactin levels on October 29 were 1.2 and 68.1 ng/ml. Menstruation began on November 4.

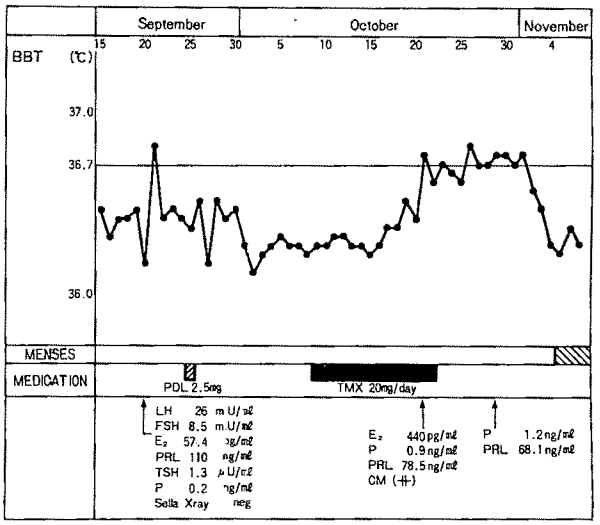

Fig. 1. Graph showing basal body temperature, menses, and effects of medication on hormone levels.

Comment

In rats, it was reported that continuous exposure to estradiol causes decreased tyrosine hydroxylase activity in the hypothalamus and a fall in dopamine levels. These changes, however, appeared to be reversible, with the catecholamine production restored and prolactin levels normalized[1] if estradiol was removed. The effect of tamoxifen citrate in the present study therefore may well be due to the blockade of estradiol action

at the hypothalamic level and a recovery of dopaminergic function, although a direct effect of tamoxifen citrate may have modified the secretory function of the lactotropes to decrease prolactin, which in turn reestablished normal pulsatile luteinizing hormone–releasing hormone secretion from the higher neuronal center.[2]

To our best knowledge, this is the first report of successful induction of ovulation in a hyperprolactinemic women with the use of tamoxifen citrate alone. Recently one study appeared in which patients with pituitary microadenoma were successfully treated with bromocriptine and tamoxifen citrate but treatment was required for a period of several months.[3] Since our patient had only 2 months of amenorrhea with moderately elevated prolactin levels and responded to tamoxifen citrate alone, it was suggested that the early pathogenic process of the disease might at least be related to chronic estradiol output from the ovaries. In fact estradiol levels in the present case (57.4 pg/ml) are compatible with those in the midfollicular phase and not considered "hypoestrogenic."

A shorter tamoxifen citrate regimen may lessen subsequent low ovarian progesterone output (luteal defect) and improve its use in a clinical practice.

Modulating actions of estradiol on gonadotropin-releasing hormone–stimulated prolactin secretion in postmenopausal individuals

Elisabeth Christiansen, M.D., Johannes D. Veldhuis, M.D., Alan D. Rogol, M.D., Ph.D., Paul Stumpf, M.D., and William S. Evans, M.D.

Charlottesville, Virginia, and Neptune, New Jersey

The temporal aspects of estrogen treatment on serum prolactin concentrations basally and in response to a 10 μg intravenous injection of gonadotropin-releasing hormone were assessed in eight postmenopausal women. The response of prolactin to gonadotropin-releasing hormone stimulation was compared with that of follicle-stimulating hormone and luteinizing hormone obtained simultaneously. Basal serum prolactin increased significantly ($p < 0.001$) in response to estrogen treatment, and a positive correlation was found between the serum concentrations of estradiol and prolactin ($r^2 = 0.266$; $p = 0.0011$). Gonadotropin-releasing hormone induced a significant increase in serum prolactin concentrations, which was greater after 5 to 10 days of estrogen treatment compared with that in the estrogen-depleted state ($p = 0.031$). No correlation was found between gonadotropin-releasing hormone–stimulated prolactin and luteinizing hormone or follicle-stimulating hormone release. These data demonstrate that estrogen treatment of previously hypoestrogenemic postmenopausal women potentiates gonadotropin-releasing hormone–stimulated prolactin release. Furthermore, our data suggest that the previously described paracrine interaction between the gonadotropens and lactotropes exerted by gonadotropin-releasing hormone does not appear to be mediated via increased gonadotropin release. (Am J Obstet Gynecol 1987;157:320-5.)

Key words: Prolactin, estradiol, gonadotropin-releasing hormone

Several lines of evidence suggest a strong relationship between prolactin secretion and the ambient concentration of estrogen. During the menstrual cycle, prolactin concentrations supposedly enhance coincident with relatively high circulating estrogen levels, such as just before the preovulatory luteinizing hormone (LH) surge[1] and in the middle of the luteal phase.[2] In men[3,4] and in postmenopausal women[5-7] increased basal circulating prolactin concentrations have been measured during estrogen treatment and appear to be dose related.[6] Moreover, recent studies in postmenopausal women and women with normal cycles[8-10] and in men[4] have defined enhanced prolactin secretion after gonadotropin-releasing hormone (GnRH) stimulation. However, the relationship between estrogen and GnRH-stimulated prolactin secretion remains controversial. Indeed, estrogens have been suggested to decrease,[10] increase,[4] or have no effect[8] on GnRH-stimulated prolactin secretion. Although the mechanism by which GnRH influences prolactin release is unknown, evidence has recently been presented to suggest a paracrine action of the gonadotropes on the lactotropes,[11] perhaps with follicle-stimulated hormone (FSH)–enriched gonadotropes mediating this process.[10]

We recently reported the effects of estradiol 17β, administered to postmenopausal women via a Silastic intravaginal ring on both circulating sex steroid concentrations[12] and on the stimulation of LH by GnRH.[13] We have now extended the study to (1) evaluate the temporal aspects of estrogen treatment on basal and GnRH-stimulated prolactin secretion in previously hypoestrogenic postmenopausal individuals and (2) examine the relationship between GnRH-stimulated gonadotropin and prolactin release in hypoestrogenic and estrogen-treated postmenopausal

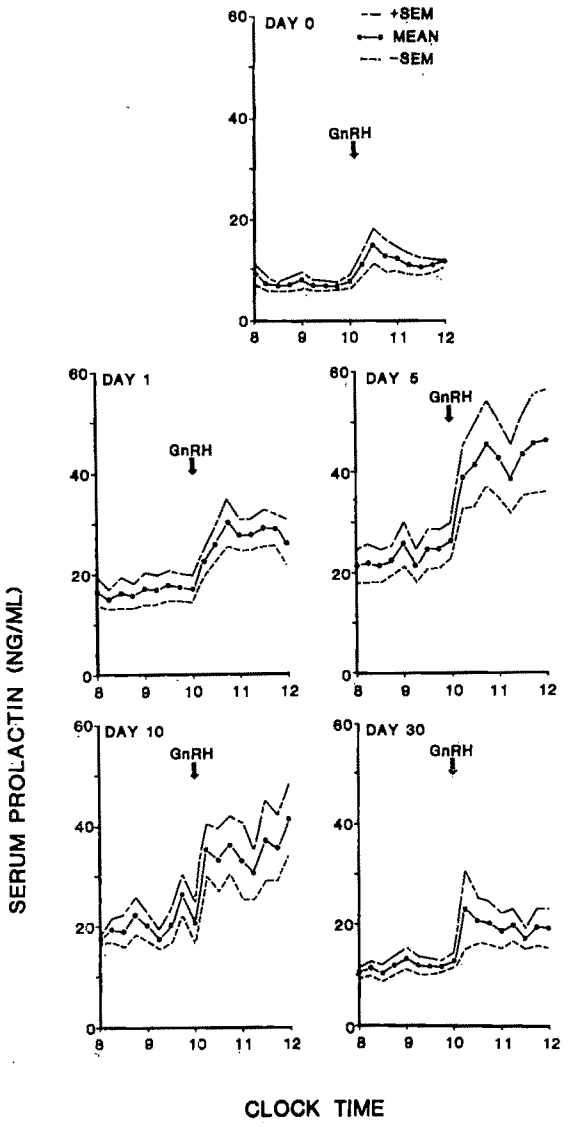

Fig. 1. Temporal profiles of serum prolactin concentrations (*ng/ml*; ±SEM) in postmenopausal women sampled at 15-minute intervals for 4 hours before estrogen treatment and on days 1, 5, 10, and 30 after intravaginal placement of a Silastic ring that contained 400 mg pure estradiol 17β. The first 2 hours of blood sampling represents basal conditions (8:00 to 10:00). A 10 μg intravenous bolus injection of GnRH was administered at 10:00 on each study day.

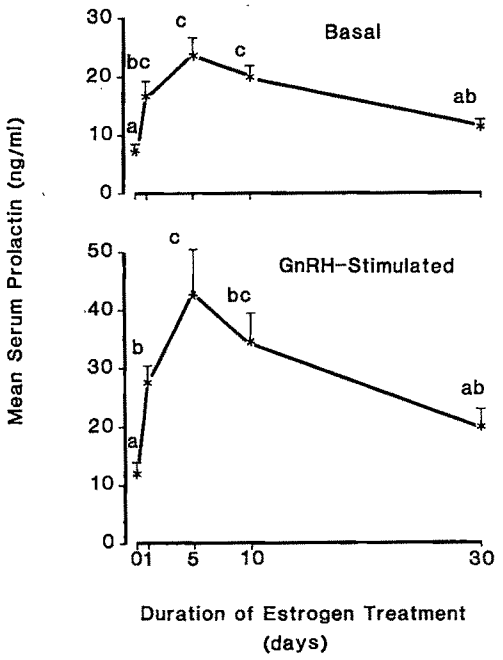

Fig. 2. Mean serum concentrations of prolactin before (day 0) and on days 1, 5, 10, and 30 of estradiol administration via an intravaginal Silastic ring. The 2-hour mean serum prolactin concentrations *(ng/ml)* are depicted for baseline conditions (top panel) and after GnRH stimulation (bottom panel). Differing labels *(a, b, c)* denote significant differences within each graph by analysis of variance ($p < 0.05$).

women. To this end, serial serum concentrations of prolactin and gonadotropins were determined basally and after a bolus injection of GnRH. Studies were performed before and at intervals (1, 5, 10, and 30 days) during the administration of estrogen.

Material and methods

Subjects. Eight healthy postmenopausal women aged 55 to 63 years (median 58 years) participated in the study, which was an extension of previously published work.[13] No subject had been treated with estrogen for at least 5 weeks before the study. Each subject had normal hepatic, renal, and hematologic function, normal thyroid hormone levels, and gonadotropin concentrations in the postmenopausal range. Written informed consent, approved by the Human Investigation Committee at the University of Virginia, was obtained before initiation of these studies.

Methods. Subjects were admitted to the Clinical Research Center at the University of Virginia on five occasions. During each admission blood samples were withdrawn at 15-minute intervals for 4 hours from 8:00 AM to 12:00 noon, through an indwelling heparin-lock cannula that was inserted 1 hour before initiation of blood sampling. An intravenous bolus injection of 10 μg GnRH (Factrel) was given at 10:00. Studies were undertaken basally (before estrogen treatment) and on days 1, 5, 10, and 30 of estradiol 17β replacement delivered via an intravaginal Silastic ring that contained 400 mg of estradiol 17β.[12-14]

Assays. All blood samples were assayed for prolactin in duplicate by radioimmunoassay as previously described.[15] Intraassay and interassay coefficients of variation were 8.3% and 8.9% at 6.6 ng/ml and 8.4% and 14.5% at 76.1 ng/ml. LH and FSH concentrations in

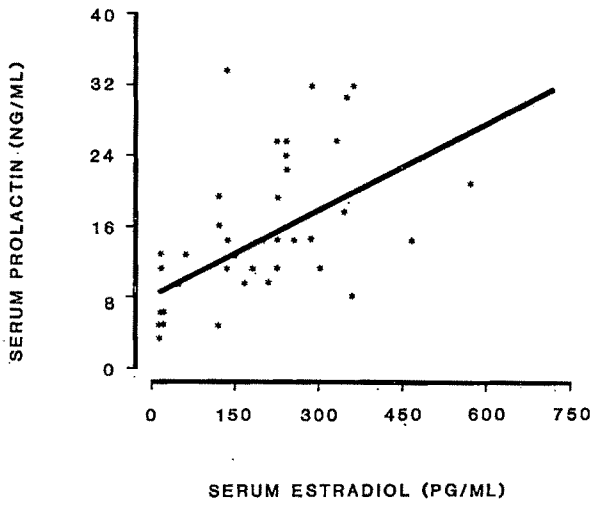

Fig. 3. Mean baseline serum prolactin was significantly and positively correlated ($r^2 = 0.266$; $p = 0.0011$) with the circulating level of estradiol obtained in postmenopausal women before and during estradiol replacement.

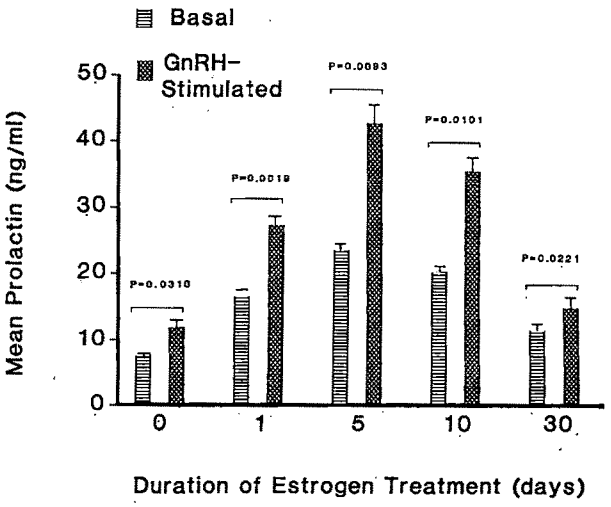

Fig. 4. Mean serum prolactin concentrations *(ng/ml)* in the estrogen-depleted state (day 0) and on days 1, 5, 10, and 30 of estrogen replacement in postmenopausal women. Blood samples were drawn every 15 minutes for 4 hours on each occasion. The first 2 hours represent basal conditions *(line bars)*, and the last 2 hours represent after-intravenous administration of 10 μg of GnRH *(fence bars)*.

the blood samples have previously been reported.[13] Serum estradiol was measured by specific radioimmunoassay as described.[16]

Data analysis. The effects of estrogen on prolactin concentrations in different sessions (days 0, 1, 5, 10, and 30) were assessed by analysis of variance with Duncan's multiple range test. Comparison of prolactin secretion basally and in response to GnRH stimulation was made by paired Student's *t* test. Correlations between serum estradiol and mean prolactin concentrations basally and in response to GnRH were sought by linear regression. Linear regression was also used to test for significant correlations between (1) mean increments in serum prolactin and the corresponding FSH, LH, and FSH/LH levels on each of the study days and (2) percent of maximal prolactin increments and percent of maximal FSH, LH, and FSH/LH increments.

Results

Serum estradiol. Before placement of the vaginal ring that contained estradiol, the mean serum estradiol concentration was 14.1 ± 3.5 pg/ml ± SEM. After the first 24 hours of estrogen treatment, this value increased significantly ($p < 0.0001$) to a maximum of 340 ± 44.2. Serum estradiol levels decreased gradually during the rest of the treatment period with concentrations of 253 ± 29.2 (day 5), 213 ± 26.2 (day 10), and 158 ± 24.5 (day 30), all of which were significantly elevated compared with levels before treatment ($p = 0.0001$).

Basal and GnRH-stimulated prolactin release and effect of estradiol. Fig. 1 shows the temporal profiles of mean serum prolactin levels derived from eight postmenopausal women who had blood samples taken at 15-minute intervals for 4 hours (beginning at 8:00) before estrogen treatment (day 0) and on days 1, 5, 10, and 30 of estradiol administration. A GnRH bolus injection was given at 10:00 on each study day as indicated.

Mean basal serum prolactin levels were obtained for the 2-hour intervals preceding administration of GnRH (8:00 to 10:00) for each of the five study sessions. As shown in the top panel of Fig. 2, basal serum prolactin concentrations increased significantly within 24 hours of estrogen treatment ($p = 0.005$). Although there was a trend toward an enhanced prolactin concentration on day 5, there were no significant differences between days 1, 5, and 10. By day 30 of estrogen treatment, the mean basal serum prolactin concentration was between the levels seen basally and on day 1. The circulating estradiol concentration was significantly and positively correlated ($r^2 = 0.266$; $p = 0.0011$) with mean basal serum prolactin levels during the entire time course (Fig. 3).

Mean levels of serum prolactin obtained after the GnRH bolus injection (10:15 to 12:00) on each of the 5 days of the study are shown in the bottom panel of Fig. 2. Compared with levels obtained before treatment with estrogen, mean serum GnRH-stimulated prolactin levels increased significantly ($p = 0.027$) after 24 hours of estrogen treatment, and this increase was followed by an additional increase by day 5 ($p = 0.026$). There

Table I. Mean increments above basal in prolactin, FSH, LH, and FSH/LH levels after GnRH stimulation

Estrogen treatment (days)	*Prolactin (ng/ml)*	*LH (mIU/ml)*	*FSH (mIU/ml)*	*FSH/LH*
0	4.6 ± 1.7[a]	41.3 ± 6.3[a]	23.6 ± 4.0[a]	0.54 ± 0.03[a]
1	10.7 ± 2.2[a,b]	33.2 ± 6.5[a]	17.4 ± 2.9[a]	0.54 ± 0.04[a]
5	19.3 ± 5.4[b]	37.8 ± 5.3[a]	20.6 ± 2.5[a]	0.56 ± 0.04[a]
10	17.1 ± 4.2[b]	42.0 ± 4.0[a]	20.6 ± 2.5[a]	0.48 ± 0.03[a]
30	8.4 ± 2.7[a,b]	21.6 ± 4.6[a]	14.8 ± 2.5[a]	0.74 ± 0.05[b]

All values are mean ± SEM. Differing superscripts (a,b) denote significant differences ($p < 0.05$) within columns by analysis of variance.

was no difference between GnRH-stimulated prolactin levels on days 5 and 10 or on days 1 and 10. By day 30 of estrogen treatment, the prolactin response to GnRH was similar to that obtained before administration of estrogen and that on day 1. A significant positive correlation was found between the ambient levels of serum estradiol and mean serum prolactin concentrations after GnRH stimulation ($r^2 = 0.181$; $p = 0.0078$; data not shown).

Comparison of basal and GnRH-stimulated prolactin, LH, and FSH release. Administration of GnRH induced a significant increase in mean serum prolactin concentrations on all study days (Fig. 4). However, the mean prolactin increments above basal were significantly higher ($p = 0.031$) on days 5 and 10 of estrogen treatment compared with those obtained in the estrogen-depleted state (Table I). Also shown in Table I are mean increments above basal in FSH, LH, and FSH/LH levels after administration of GnRH during each of the five study sessions. There was no significant difference in mean increments of FSH and LH among study days, but the FSH/LH level was higher on day 30 of estrogen treatment than on any other study day. To compare the prolactin and gonadotropin release after administration of GnRH, linear regression analysis was done between mean prolactin increments and the corresponding mean FSH, LH, and FSH/LH increments on individual study days. No significant correlations were obtained in either the estrogen-depleted state or during estrogen treatment. Likewise, we were unable to document any correlations between maximal percent of increments in serum prolactin concentrations and the corresponding FSH, LH, and FSH/LH levels (data not shown).

Comment

The present study confirms previous observations in postmenopausal women that administration of estrogen is associated with an increase in basal serum prolactin concentrations[5, 7] and that GnRH stimulation can effect an increase in circulating prolactin in the estrogen-deprived woman.[8, 10] In addition, we present evidence that administration of estrogen to postmenopausal women potentiates the prolactin response to GnRH stimulation without resulting in a parallel increase in gonadotropin release.

After reaching maximal concentrations within 24 hours after placement of the vaginal ring, serum estradiol levels decreased by day 5 of treatment, and throughout the rest of the treatment period they remained in the range typically observed during the late follicular phase of the menstrual cycle.[12, 13] The rise in circulating prolactin was prompt, increasing twofold after 24 hours of treatment and reaching a peak by day 5. Although we found a highly significant positive correlation between circulating concentrations of estradiol and prolactin, there appeared to be a time lag in the peak concentrations of the two hormones. Our results provide a detailed time course, which is in general agreement with the data obtained by Yen et al.[5] in four hypogonadal women, and showed an almost fourfold increase in serum prolactin levels after 2 weeks of orally administered ethinyl estradiol (1μg/kg/day). Moreover, our results on day 10 of estradiol administration are consistent with those of Joseph et al.,[7] who recently described a threefold increment in circulating prolactin levels after 10 days of intramuscular administration of estradiol benzoate (0.625 mg/day) in 10 postmenopausal women.

GnRH clearly stimulated prolactin secretion in the estrogen-depleted state. During estrogen treatment an enhanced prolactin response to GnRH was observed, which suggests that estrogen potentiates the prolactin-stimulating effect of GnRH. When Yen et al.[8] compared the effect of a GnRH agonist on circulating prolactin levels in hypogonadal women and in women at random stages of the menstrual cycle, no difference in the magnitude of prolactin response to the agonist was found between the two groups. In a later study Zhang and Yen[9] demonstrated that whereas a GnRH agonist elicited a significant increase in serum prolactin concentrations in postmenopausal women, no prolactin-stimulating effect of the agonist was found in normal young men. More recently, Mais and Yen[10] described a significant prolactin increment after administration of GnRH (10 μg intravenously) in a group of hypergo-

nadotropic hypogonadal women. In contrast, two of seven women in the early follicular phase of the menstrual cycle had a small response, even though the circulating estradiol levels were similar in the two groups. Accordingly, it is possible that the differences in prolactin responsiveness to the administration of GnRH may be attributed to intrinsic modulating factors such as endogenous GnRH secretion or the prevailing levels of sex steroid hormones.[17] We found not only that administration of estrogen potentiates the prolactin response to GnRH stimulation but also that there is a significant positive correlation between the serum estradiol concentration and GnRH-stimulated prolactin release. A likely role for sex steroids as modulators of the prolactin response to GnRH is also supported by the findings of Barbarino et al.,[4] who administered estrogen intramuscularly over a 9-day period to castrated and noncastrated men and measured the prolactin reponse to GnRH stimulation before and on the last day of treatment. No change in prolactin concentrations was noted in the absence of estrogen, whereas estrogen treatment induced a significant increase in the serum prolactin concentration, which was greater in the castrated than in the noncastrated men.

Although the mechanisms subserving the estrogen-associated elevation in circulating levels of prolactin remain ill-defined, they may involve a direct effect on prolactin synthesis[18] and/or lactotrope hyperplasia. Similarly, the process through which GnRH stimulates prolactin release is subject to conjecture. It has been suggested that GnRH may affect prolactin release through a central catecholaminergic mechanism[19] or via direct stimulation of pituitary lactotropes. However, one of the more intriguing mechanisms proposed is that of a paracrine interaction between the gonadotropes and the lactotropes.[11] In vitro studies have demonstrated that gonadotropes secrete a substance or substances with prolactin-releasing activity, the nature of which has yet to be determined.[11] A role for LH α-subunit as a possible mediator in GnRH induction of lactotropes has been suggested by Begeot et al.[20] However, more recent studies by Mais and Yen[10] have focused on a population of FSH-enriched gonadotropes as putative generators of a paracrine action on lactotropes. They found a significant positive correlation between maximal percent of prolactin increments after administration of GnRH (10 μg intravenously) and the ratio of FSH to LH maximal percent of increments in six hypergonadotropic hypogonadal women. Our results are at variance with this observation in that we were unable to demonstrate any correlation between prolactin and FSH to LH ratio with respect to mean increments or maximal percent of increments after a similar GnRH bolus injection in eight hypoestrogenic and estrogen-treated postmenopausal women studied serially after estradiol replacement. In addition, we found no correlation between GnRH-stimulated mean prolactin increments and mean increments in FSH or LH, which suggests that neither FSH nor LH release per se mediates the effect on GnRH on lactotropes. Our findings are supported by in vitro culture studies by Denef,[11] in which FSH and LH did not directly influence prolactin release.

Increased thromboxane biosynthesis in normal pregnancy is mainly derived from platelets

D. J. Fitzgerald, M.B., G. Mayo, R.N., F. Catella, M.D., S. S. Entman, M.D., and G. A. FitzGerald, M.D.

Nashville, Tennessee

Thromboxane biosynthesis was determined in normal pregnant subjects by measurement of its major urinary and plasma metabolites, 2,3-dinor-thromboxane B_2 and 11-dehydro-thromboxane B_2. Urinary 2,3-dinor-thromboxane B_2 increased early in pregnancy (731 ± 124 pg/mg creatinine) compared with nonpregnancy (<350 pg/mg creatinine; $p < 0.001$) and the postpartum period (155 ± 42 pg/mg creatinine, $p = 0.015$) and remained elevated throughout gestation. Similarly, plasma and urinary 11-dehydro-thromboxane B_2 were increased in pregnancy. To determine the cellular origin of the increase in thromboxane biosynthesis in pregnancy, platelet cyclooxygenase was selectively inhibited with aspirin in a dose of 120 mg orally followed by 20 mg twice daily for 7 days ($n = 4$). Selectivity was confirmed by measurement of urinary 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$, an index of prostacyclin biosynthesis. Coincident with a 97% inhibition of serum thromboxane B_2, urinary 2,3-dinor-thromboxane B_2 was almost completely inhibited and paralleled the recovery of platelet cyclooxygenase after withdrawal of aspirin. This study demonstrates that thromboxane biosynthesis is increased in pregnancy. The increase is mainly platelet derived and is consistent with increased platelet activation throughout pregnancy. (Am J Obstet Gynecol 1987;157:325-30.)

Key words: Pregnancy, thromboxane, prostacyclin, platelets

Platelet activation is enhanced in normal pregnancy as part of a generalized coagulopathy resulting in an increased risk of thrombosis.[1] What mediates the increase in platelet activity in pregnancy is unknown. Formation of thromboxane A_2, the major cyclooxygenase product of arachidonic acid in platelets and a potent platelet aggregant,[2] is reported to be increased in pregnancy.[3, 4] A possible source of increased thromboxane formation in pregnancy is the placenta, which has been shown to generate thromboxane in vitro.[5] However, estimates of thromboxane formation in pregnancy have been based on measurement of plasma immunoreactive thromboxane B_2, the hydrolysis product of thromboxane A_2. This approach is highly subject to both sampling and analytical artifact.[6] If thromboxane biosynthesis is indeed increased during pregnancy, an alternative source might be the platelet, the predominant origin of thromboxane A_2 generation in nonpregnant individuals.[7] We have previously demonstrated increased thromboxane formation in a number of conditions associated with platelet activation, including severe ath-

erosclerosis and unstable angina.[8] Platelet activation is also frequently associated with an increase in the formation of prostacyclin,[8, 9] the major cyclooxygenase products of arachidonic acid in endothelium and a potent inhibitor of platelet aggregation.[10] This increase in prostacyclin formation may represent a local compensatory mechanism by vascular endothelium to platelet activation. We have previously reported an increase in prostacyclin formation in normal pregnancy.[11] Although prostacyclin can be generated by the placenta,[5] the source of the increment in prostacyclin biosynthesis during pregnancy is uncertain. It is possible that it represents a vascular response to platelet activation.

In the present study we prospectively determined thromboxane A_2 biosynthesis in normal pregnancy by measurement of its major urinary enzymatic metabolites, 2,3-dinor-thromboxane B_2 and 11-dehydro-thromboxane B_2,[12, 13] and by measurement of its most abundant plasma metabolite, 11-dehydro-thromboxane B_2. Measurement of these metabolites avoids the problems of invasive sampling.[6, 13] Furthermore, the physicochemical methods that we used are highly sensitive and specific and avoid the analytic errors inherent in assays based on immunologic measurements.[6] To address the cellular origin of thromboxane biosynthesis during pregnancy we used selective inhibition of platelet cyclooxygenase.

Methods

The study group consisted of pregnant subjects attending the obstetrics clinic at Vanderbilt University prior to 20 weeks' gestation. All subjects gave informed written consent and the study was approved by the Committee for the Protection of Human Subjects at Vanderbilt University. All subjects were healthy at the time of admission into the study. Patients with a previous history of diabetes or renal disease were excluded. All subjects were asked to refrain from taking any medications during the study, in particular, aspirin or other nonsteroidal anti-inflammatory drugs. Patients attended the clinic at 2- to 4-week intervals. At each visit urine was analyzed for protein (Dipstick) and blood pressure was recorded in the sitting position using a standard mercury sphygmomanometer, with phase V of the Korotkoff sounds being recorded as the diastolic end point. Patients were excluded if they developed hypertension, diabetes, or intrauterine growth retardation. Collections of 24-hour urine samples were made at <20 weeks, at 20 to 28 weeks, at 28 weeks to term, and after 6 weeks post partum for determination of the urinary thromboxane metabolite 2,3-dinor-thromboxane B_2. Samples from the last trimester and the postpartum period were also analyzed for urinary 11-dehydro-thromboxane B_2. In a subset of patients blood was withdrawn in the third trimester with an 18-gauge needle in a syringe containing heparin, 100 units/ml, for determination of plasma 11-dehydro-thromboxane B_2, the most abundant metabolite of thromboxane B_2 in plasma.

To determine the major source of thromboxane A_2 biosynthesis in pregnancy, aspirin was administered orally in a loading dose of 120 mg followed by 20 mg twice daily for 7 days at 32 to 36 weeks' gestation in four normotensive pregnant women. Excretion of 2,3-dinor-thromboxane B_2 and 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ was determined in 24-hour urine samples before and during drug administration and during the 7-day period after withdrawal of aspirin. Similarly, serum thromboxane B_2 was determined in peripheral venous samples before and during aspirin administration and after drug withdrawal.

Biochemical analysis. Urine was analyzed for 2,3-dinor-thromboxane B_2 and 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ by combined gas chromatography–negative ion chemical ionization–mass spectrometry with their tetradeuterated isotopes used as internal standards. For determination of 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$, 5 ng of tetradeuterated standard was added to a 5 ml aliquot of urine and the sample was stored at −20° C until it was analyzed. After extraction and back extraction under alkaline and acidic conditions, the sample was derivatized as the methoxime, pentafluorobenzyl ester. After further purification on silica gel thin-layer chromatography platelets (Whatman Chemical Separation Inc., Clifton, New Jersey) derivatization was completed by formation of the trimethylsilyl ether derivative. Quantitation was accomplished by stable isotope dilution with a Hewlett Packard 5980 instrument operated in the negative ion mode, monitoring m/z 586 for endogenous 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ and m/z 590 for the deuterium-labeled internal standard. For determination of 2,3-dinor-thromboxane B_2, 7.25 ng of internal standard was added to a 5 ml aliquot of urine and the sample was derivatized as the methoxime derivative. After extraction by bonded-phase phenyl boronic acid column and further purification by C-18 Sep-Pak (Waters Associates, Milford, Massachusetts) and thin-layer chromatography the sample was derivatized as the methoxime, pentafluorobenzyl ester. Derivatization was completed after further thin-layer chromatography by formation of the trimethysilyl ether. Analysis was by gas chromatography–negative ion chemical ionization–mass spectrometry with the use of a capillary column interfaced with a Nermag R10-10C and monitoring m/z 586.5 for endogenous 2,3-dinor-thromboxane B_2 and m/z 590.5 for the tetradeuterated internal standard. Repeat measurements of 2,3-dinor-

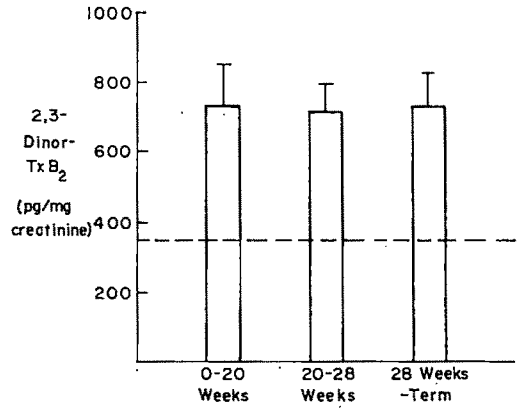

Fig. 1. Urinary excretion of 2,3-dinor-thromboxane B_2 *(TxB₂)* in pregnant subjects (n = 18) throughout gestation compared with nonpregnant subjects ($p < 0.001$). The *hatched line* represents the upper limit of normal (95% upper confidence limit) in normal nonpregnant women.

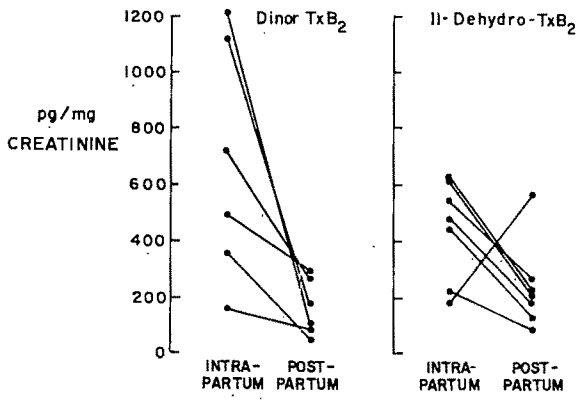

Fig. 2. Comparison of urinary 2,3-dinor-thromboxane B_2 *(Dinor TxB₂)* (n = 6; p = 0.015) and 11-dehydro-thromboxane B_2 *(11-Dehydro-TxB₂)* (n = 7; p = 0.029) in the last trimester and in the postpartum period.

thromboxane B_2 in 24-hour urine samples collected over five successive days in four pregnant subjects showed good day-to-day reproducibility with a coefficient of variation of 23% ± 9%.

Plasma was analyzed for 11-dehydro-thromboxane B_2 according to methods similar to those used for determining urinary metabolites.[13] Briefly, 5 ng of deuterated internal standard was added to 10 ml of plasma. After acidification, the sample was extracted by C-18 Sep-Pak, eluted with ethyl acetate and further purified by thin-layer chromatography. The sample was derivatized as the pentafluorobenzyl ester and after a further thin-layer chromatography step derivatization was completed by trimethylsilylation. Quantitation was as for 2,3-dinor-thromboxane B_2 monitoring m/z 511 for endogenous 11-dehydro-thromboxane B_2 and m/z 515 for the tetradeuterated internal standard.

Serum thromboxane B_2 was determined by a modification of the method of Fitzpatrick et al.[14] after incubation of 3 ml of whole blood in a glass test tube at 37° C for 45 minutes.

Statistical analysis. All data are expressed as the mean ± SEM. The data were analyzed by Kruskal-Wallis analysis of variance and subsequent comparison between groups was performed by the Wilcoxon rank-sum test for paired and unpaired data as appropriate. These are nonparametric tests that avoid assumptions as to the distribution of the data.

Results

Eighteen patients, seven black and 11 white, with a mean age of 22.3 ± 1.0 years were prospectively studied throughout gestation. Nine of our subjects were primigravid. All of our subjects remained normotensive and had normal deliveries with a mean birth weight of 7.17 ± 0.3 pounds. Urinary 2,3-dinor-thromboxane B_2 was increased at less than 20 weeks (731 ± 124 pg/mg of creatinine) and remained elevated throughout pregnancy (714 ± 81 and 726 ± 104 pg/mg of creatinine, respectively, at 20 to 28 weeks and 28 weeks to term) when compared with normal nonpregnant levels (<350 pg/mg of creatinine; $p < 0.001$, Fig. 1) or with levels in the postpartum period (155 ± 42 pg/mg of creatinine; $p = 0.015$, Fig. 2). In addition to an increase in 2,3-dinor-thromboxane B_2, urinary excretion of 11-dehydro-thromboxane B_2 was increased in all but one pregnant subject studied in the third trimester (440 ± 67 pg/mg creatinine) when compared with the level found in urine collected at more than 6 weeks post partum (233 ± 59 pg/mg of creatinine; $p = 0.029$, Fig. 2). Consistent with this observation, plasma 11-dehydro-thromboxane B_2 was increased in the third trimester when compared with levels found in nonpregnant normal subjects (3.2 ± 0.76 versus 1.3 ± 0.16 pg/ml; $p = 0.016$, Fig. 3).

Administration of aspirin was associated with a marked reduction in serum thromboxane B_2, the peak effect occurring on day 7 with a mean inhibition of 97% from pretreatment levels (Fig. 4). Withdrawal of aspirin resulted in the gradual recovery of platelet cyclooxygenase with a mean inhibition of only 13% of serum thromboxane B_2 by 7 days after withdrawal. Consistent with the platelet being the major source of thromboxane biosynthesis in vivo in these subjects, urinary 2,3-dinor-thromboxane B_2 followed a similar pattern, with a mean inhibition of 94% by day 7 of aspirin therapy and a gradual recovery after aspirin withdrawal (Fig. 4). Excretion of 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ was increased (mean and range, 1564 and 531 to 3505 pg/mg of creatinine) in all four subjects

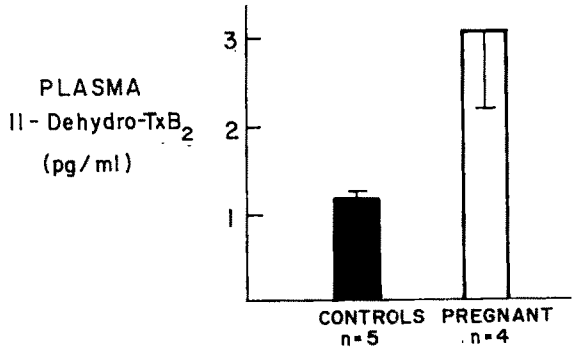

Fig. 3. Comparison of plasma 11-dehydro-thromboxane B_2 *(11-Dehydro-TxB$_2$)* in pregnant (n = 4) and nonpregnant (n = 5; p = 0.016) subjects.

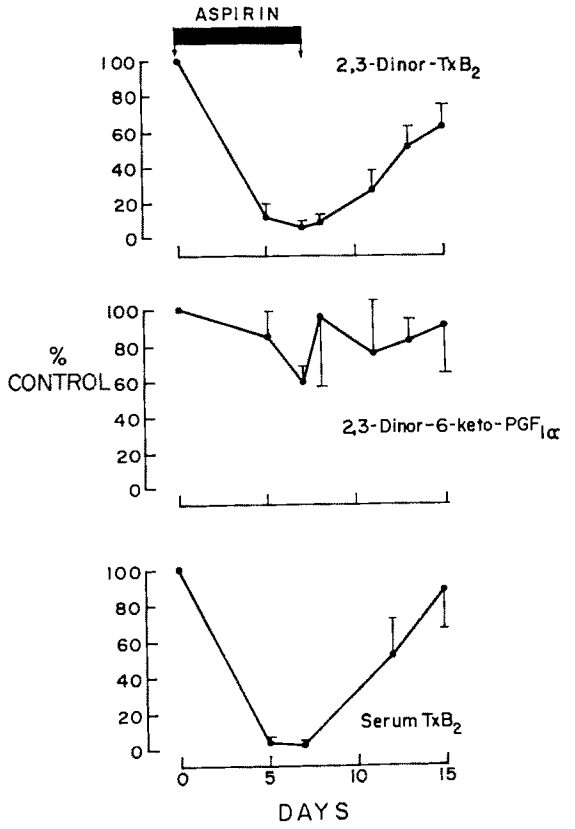

Fig. 4. Excretion of urinary 2,3-dinor-thromboxane B_2 *(2,3-Dinor-TxB$_2$)*, 2,3-dinor-prostaglandin $F_{1\alpha}$ *(2,3-Dinor-6-keto-PGF$_{1\alpha}$)* and serum thromboxane B_2 *(Serum TxB$_2$)* in normal pregnant subjects (n = 4) before, during, and after administration of 120 mg of aspirin orally followed by 20 mg twice daily for 7 days.

when compared with nonpregnant levels (<220 pg/mg creatinine), as is seen in normal pregnancy. Administration of aspirin resulted in a mean inhibition of 15% of urinary 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ by day 5 and a mean inhibition of 40% by day 7 of therapy. These changes did not, however, achieve statistical significance.

Comment

These studies demonstrate an increase in urinary 2,3-dinor-thromboxane B_2 in normal pregnant subjects that occurs early in and persists throughout gestation. Previous studies demonstrate that 2,3-dinor-thromboxane B_2 is a major urinary metabolite of thromboxane B_2, the nonenzymatic hydrolysis product of thromboxane A_2.[15] Thus these findings suggest that thromboxane biosynthesis is increased in normal pregnancy. To address the possibility that the increased excretion of 2,3-dinor-thromboxane B_2 reflected preferential metabolism of thromboxane B_2 to this metabolite in pregnancy and not an increase in thromboxane formation, we measured excretion of 11-dehydro-thromboxane B_2, which represents a second major pathway of thromboxane B_2 enzymatic metabolism.[12, 13] Consistent with the urinary 2,3-dinor-thromboxane B_2 data, excretion of 11-dehydro-thromboxane B_2 was increased in pregnant subjects compared with the levels found post partum. Another possible mechanism for the increase in urinary thromboxane metabolites is an increase in renal clearance during pregnancy. For this reason the data were corrected for urinary creatinine. In addition, plasma 11-dehydro-thromboxane B_2 was also increased in pregnancy, which demonstrates that the increase in urinary metabolites reflected increased formation and not simply an increase in their renal clearance. In any event, at steady state, urinary excretion of thromboxane B_2 metabolites will equal their generation and will be independent of renal function. Thus the increase in 2,3-dinor-thromboxane B_2 excretion in our subjects reflected an increase in thromboxane biosynthesis in pregnancy and not an alteration in thromboxane B_2 metabolism or renal function.

In nonpregnant subjects, the major source of urinary 2,3-dinor-thromboxane B_2 is platelet-derived thromboxane.[7] Thus selective inhibition of platelet cyclooxygenase results in a marked reduction in urinary 2,3-dinor-thromboxane B_2 excretion.[7] Similar studies suggest that 11-dehydro-thromboxane B_2 in urine is also mainly derived from platelet thromboxane (Catella F, FitzGerald GA, unpublished data). It has been suggested that the placenta forms thromboxane and that this may play a role in modulating umbilical blood flow.[3] Thus the increase in thromboxane formation in pregnancy may be partly derived from the placenta. To determine the predominant source of the increment in thromboxane formation in pregnancy we examined thromboxane metabolite excretion after administration of a low-dose aspirin regimen that would selectively inhibit platelet cyclooxygenase. Inhibition of platelet

cyclooxygenase was monitored by determination of serum thromboxane B_2, a measure of the capacity of platelets to generate thromboxane A_2. After 5 days of treatment, serum thromboxane B_2 was almost completely inhibited. Coincident with the inhibition of platelet cyclooxygenase, there was a marked reduction in 2,3-dinor-thromboxane B_2 excretion. That this reflected inhibition of platelet cyclooxygenase was supported by two additional findings. First, excretion of 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$, the major urinary metabolite of prostacyclin,[6] was inhibited minimally and only transiently. Urinary 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ is increased in normal pregnancy, which reflects an increase in prostacyclin biosynthesis[11] and is an index of tissue cyclooxygenase activity. Thus this dose of aspirin appears to be relatively selective for platelet cyclooxygenase. Second, the recovery of 2,3-dinor-thromboxane B_2 excretion paralleled the recovery of platelet cyclooxygenase. Aspirin irreversibly inhibits the cyclooxygenase enzyme so that recovery is dependent on the formation of new enzyme.[16] Tissue cyclooxygenase recovers rapidly through formation of new protein. However, the anucleate platelet cannot generate new enzyme so that recovery of platelet cyclooxygenase and therefore of serum thromboxane B_2 is dependent on the generation of new platelets. Since platelets have a half-life of about 5 days, serum thromboxane B_2 increases gradually after aspirin withdrawal, returning to normal at about 10 days.[17] Thus the delayed recovery of urinary 2,3-dinor-thromboxane B_2 after aspirin withdrawal in our subjects is consistent with the platelet being the major source of the increase in thromboxane biosynthesis in pregnancy.

We have demonstrated previously that thromboxane biosynthesis is increased in conditions associated with platelet activation.[8] Although some studies have suggested that platelet function is normal in uncomplicated pregnancy,[18] others have reported changes consistent with in vivo platelet activation.[1] Thus circulating platelet aggregates are increased[19] and plasma levels of the platelet granule constituent β-thromboglobulin are elevated.[20] In addition, recovery of platelet cyclooxygenase activity after a single dose of aspirin is slightly accelerated[21] and platelet volume is increased,[22] both of which are consistent with increased platelet turnover. Studies of ex vivo platelet function in pregnancy demonstrate hypoaggregability suggesting that platelets have been partially activated in vivo.[1] Thus the increase in thromboxane biosynthesis in pregnancy probably reflects increased platelet activation. As in other conditions in which there is platelet activation,[8] prostacyclin formation is increased in pregnancy. However, it is unlikely that this is due mainly to platelet activation since the increase in prostacyclin formation far exceeds the increase in thromboxane. Certainly, thromboxane-dependent platelet activation is unlikely to represent a major stimulus as prostacyclin biosynthesis is unaltered by selective inhibition of platelet cyclooxygenase by low-dose aspirin.

Previous studies have reported thromboxane formation to be increased, unchanged, or decreased in pregnancy.[3, 4] The difference between studies may in part reflect the analytic approaches that were used. A major difference between this and previous studies is that thromboxane biosynthesis was determined noninvasively with the use of methods that avoid sampling and analytic errors.[6] In many studies thromboxane formation is determined by measurement of thromboxane B_2 in plasma.[3, 4] However, the capacity of platelets to generate thromboxane exceeds by orders of magnitude the amount present in plasma. Therefore even minor degrees of platelet activation during sampling will induce formation of thromboxane A_2 and its nonenzymatic hydrolysis to thromboxane B_2. This will result in artifactually high levels of thromboxane B_2, which will obscure smaller physiologic changes.[13] Measurement of plasma and urinary enzymatic metabolites minimizes this sampling artifact.[6, 13] A second major source of error is the use of immunologic assays to measure prostanoids in the low picogram per milliliter range in biologic fluids. Cross-reactivity of the antibodies can give spurious results when one is attempting to measure minute concentrations in such systems, frequently overestimating what is present and obscuring changes in the prostanoid of interest.[6] In this study, urinary and plasma thromboxane metabolites were determined by direct physicochemical methods that avoid these analytic errors.

The role of the increase in thromboxane biosynthesis in modulating platelet activity in pregnancy is unknown. However, accelerated platelet activation precedes the development of pregnancy-induced hypertension.[23] In addition, Wallenburg et al.[24] and Beaufils et al.[25] have demonstrated that chronic inhibition of thromboxane formation with aspirin prevents the development of the disease and limits its sequelae. Together, these findings suggest a pathophysiologic role for thromboxane and platelet activation in the development of pregnancy-induced hypertension. In addition we have previously demonstrated that prostacyclin biosynthesis fails to increase normally in pregnant subjects who subsequently develop pregnancy-induced hypertension.[11] Thus the normal increase in prostacyclin formation that occurs in pregnancy may play a role in limiting platelet activation. It may be important if aspirin is to be of value in the prevention of pregnancy-induced hypertension to use a dose that inhibits platelet thromboxane formation but preserves the ability to generate prostacyclin. Although the dose of aspirin used by Wallenburg et al.[24] (60 mg) should be relatively

platelet selective, the effectiveness of this dose in inhibiting thromboxane formation and preserving prostacyclin biosynthesis was not assessed. Our studies suggest that an even smaller dose of aspirin will result in virtually complete inhibition of platelet cyclooxygenase while prostacyclin biosynthesis is maintained.

In conclusion, thromboxane biosynthesis is increased in pregnancy. The increase in thromboxane A_2 formation is mainly derived from platelets and is consistent with increased platelet activation throughout normal pregnancy.

Preeclampsia, delivery, and the hemostatic system

Abdelaziz A. Saleh, M.D., Ph.D., Sidney F. Bottoms, M.D., Robert A. Welch, M.D., Abdelkarim M. Ali, M.D., Federico G. Mariona, M.D., and Eberhard F. Mammen, M.D.

To determine the effects of preeclampsia and delivery, the hemostatic system was evaluated before and 24 to 48 hours after delivery in 59 nulliparous patients without clinical signs of disseminated intravascular coagulation. Fifteen patients with mild preeclampsia and 18 with severe preeclampsia were compared with 26 pregnant control patients. Preeclampsia was associated with high fibronectin ($p < 0.001$), low antithrombin III ($p < 0.001$), and low α_2-antiplasmin ($p < 0.005$), suggesting endothelial injury, clotting, and fibrinolysis, respectively. After delivery, fibronectin decreased only in preeclamptic patients ($p < 0.005$); α_2-antiplasmin increased in all groups ($p < 0.001$). Endothelial injury in preeclampsia appeared to resolve soon after delivery, which could contribute to the rapid clinical improvement noted in the early puerperium. (Am J Obstet Gynecol 1987;157:331-6.)

Key words: Preeclampsia, delivery, hemostatic system, fibronectin, antithrombin, antiplasmin

Recent advances in coagulation research have facilitated a better general understanding of the hemostatic system. The use of new techniques in the study of preeclampsia is of particular interest, since the cause of the occasionally associated disseminated intravascular coagulation (DIC) is unclear. However, pregnancy and delivery normally alter hemostasis, potentially confounding studies of preeclampsia.

There have been some studies with new markers for endothelial injury, clotting, and fibrinolysis to characterize hemostasis in pregnancy and/or preeclampsia. Fibronectin, a suggested marker for endothelial damage, is reported to be increased in preeclampsia.[1] Antithrombin III appears to be reduced in preeclampsia, which suggests enhanced clotting.[2,3] α_2-Antiplasmin determined by immunoassay is reported to be similar in normal pregnancy and preeclampsia, which suggests no increase in fibrinolysis.[4]

However, many questions regarding these new assays and hemostasis in pregnancy and/or preeclampsia remain unanswered. It is unclear from previous studies whether fibrin monomer, a marker for clotting, is unchanged or increased.[5,6] Assays of α_2-antiplasmin activity, more representative of biologic function than immunoassays, have not been used in pregnancy or preeclampsia. Likewise, D-dimer, which indicates the lysis of fibrin clots, has not been reported. With the exception of antithrombin III, modern coagulation technology has not been applied to determine the effect of delivery on hemostasis in normal pregnancy. Although delivery appears to be therapeutic for DIC associated with preeclampsia, none of the newer markers has been used to better understand this beneficial effect. Attempts to grasp the overall picture of hemostasis in pregnancy and preeclampsia are further hampered by the lack of studies that comprehensively evaluate the elements of hemostasis, such as platelets, endothelial injury, clotting, and fibrinolysis. Studies with new markers have rarely provided older assays, such as platelet count, fibrinogen, and fibrin(ogen) split products, to facilitate integration of new information into previously established models.

The purpose of this study is to apply recent advances in coagulation technology to comprehensively evaluate the effects of preeclampsia and delivery on hemostasis, while providing older assays for comparison.

Patients and methods

A total of 59 nulliparous patients, 33 with preeclampsia and 26 control patients of comparable gestational age were studied. Patients were chosen to exclude those with chronic hypertension, renal disease, abruptio placentae, chorioamnionitis, diabetes mellitus, multiple gestation, and other major medical and/or obstetric risks, except preeclampsia and preterm labor. The study was limited to patients without clinical signs of DIC; all cases with a bleeding diathesis, a platelet count $<100{,}000/mm^3$, a fibrinogen <100 mg/dl, an abnormally prolonged prothrombin time, or an abnormally prolonged partial thromboplastin time were excluded. During recruitment, investigators were contacted only when patients agreed to participate; the number who refused is not available. All patients indicated informed

consent on a form approved by the Human and Animal Investigation Committee of Wayne State University. Study and control patients were predominantly black and were indigent. Of the 59 gravidas, 15 had mild preeclampsia, 18 had severe preeclampsia, 44 were in labor, and 15 were not in labor. The criteria used to diagnose preeclampsia were those adopted by The American College of Obstetricians and Gynecologists.[7]

With a syringe that had a 21-gauge or larger butterfly needle, blood was obtained by venipuncture before delivery and 24 to 48 hours after delivery and was transferred into blood collection tubes (Becton Dickinson Vacutainer Systems, Rutherford, New Jersey). The first 3 ml of blood were placed in an ethylenediaminetetraacetic acid (EDTA) tube and used to measure platelet count and mean platelet volume. The next 9 ml of blood were drawn into a second syringe and transferred in equal volumes into a tube containing 0.5 ml of 3.2% sodium citrate and a second tube containing EDTA and aprotinin. Fibronectin was assayed in plasma from the second tube; all other assays were done on citrated plasma. Both tubes were centrifuged at 3000 × g for 30 minutes. Plasma was stored in small aliquots at −70° C for future analysis. The methods used for coagulation assays are outlined in Table I, and have been described in detail in previous publications.[8-10] Proteinuria was determined qualitatively (0 to 4+) with dipsticks.

Multivariate analysis of the covariance was used to evaluate the effects of preeclampsia, delivery, and their interaction on the various laboratory parameters of hemostasis, as well as the possibility of confounding factors related to labor or gestational age. Patients not in labor were believed to represent a different group from those in labor and were analyzed accordingly. Gestational age was analyzed as a covariate. Race and socio-

NS = Not significant.

economic status were not considered as confounding variables. The incidence of preeclampsia varies with these factors; controlling for them could result in underestimating the effect of preeclampsia. Equal weight was given to each cell in the analysis to avoid biases in detecting effects related only to sample size. Effects on the overall pattern of all nine parameters of hemostasis were considered significant for $p < 0.05$. In view of the multiple comparisons made in this study, effects on individual coagulation tests were considered significant for $p < 0.01$, and comparisons between individual cells were not made.

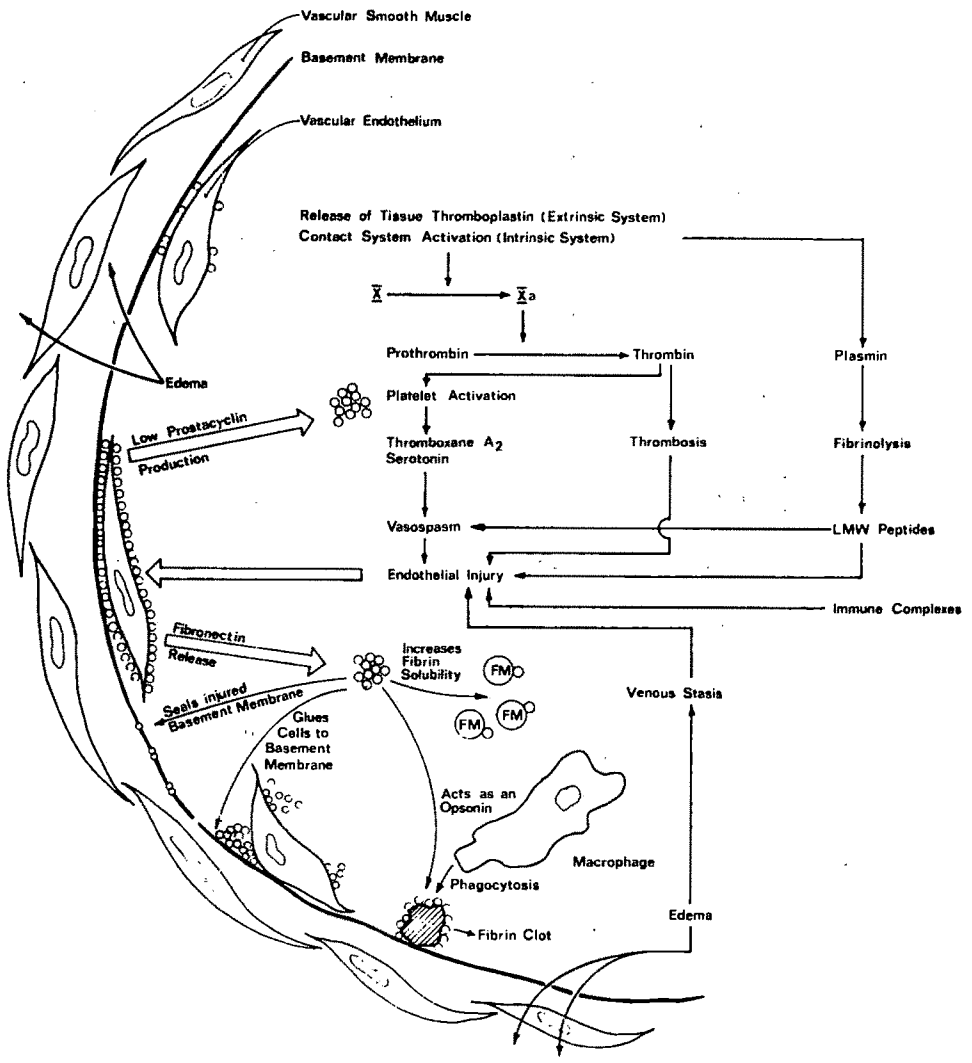

Fig. 1. A model for the effects of pregnancy-induced hypertension (preeclampsia) on the hemostatic system. Note the central role of endothelial injury. *LMW peptides* refers to low molecular weight fibrinolytic peptides; *FM* refers to fibrin monomer.

Results

The clinical characteristics described in Tables IIA and IIB are stratified according to the severity of preeclampsia and the presence of labor at the time of initial coagulation tests. The clinical changes associated with preeclampsia (hypertension, proteinuria, earlier gestational age, and lower birth weight) appeared to be more pronounced among patients recruited for the study before the onset of labor. Consequently, results stratified for preeclampsia and delivery (before or after) are reported separately for patients in labor (Table III) and those not in labor (Table IV).

Statistical analysis of the changes in hemostasis associated with preeclampsia, delivery, and their interaction is presented in Table V; potential confounding factors will be considered later. The interaction terms in this analysis can be interpreted as a measure of how the effect of delivery varies according to the presence and severity of preeclampsia. The overall terms can be interpreted as testing whether preeclampsia, delivery, or their interaction has a global effect on hemostasis, as represented by all of the laboratory parameters. Because all three overall terms were significant, the effects of preeclampsia, delivery, and their interaction on individual laboratory tests are considered in detail.

Preeclampsia was associated with an increase in fibronectin and decreases in antithrombin III and α_2-antiplasmin. Delivery was associated with a decrease in fibronectin and an increase in α_2-antiplasmin. Trends for mean platelet volume and fibrin monomer to decrease after delivery did not attain statistical significance. Decreases in fibronectin after delivery varied significantly according to the presence and severity of preeclampsia. Little change was noted in the normal

group, but progressively larger decreases were noted with mild and severe preeclampsia.

In addition to the summary presented in Table V, statistical evaluation included analysis for confounding variables related to gestational age and recruitment before labor. The parameters of hemostasis were not significantly correlated with gestational age in the 28- to 43-week range of this study ($p > 0.05$ for each parameter). Patients not in labor had similar overall coagulation profiles but had lower antithrombin III ($p < 0.01$), a change limited to preeclamptic patients. No significant interaction of recruitment before labor with preeclampsia or delivery was apparent for either overall coagulation profiles or individual parameters of hemostasis.

Comment

Taken as a whole these findings suggest that vascular endothelial injury plays a central role in the hemostatic changes associated with preeclampsia. When comparing markers of endothelial injury, clotting, and fibrinolysis, fibronectin exhibited the most pronounced changes with preeclampsia. The clinical effect of delivery specific for preeclampsia (i.e., resolution) was associated more closely with fibronectin than the other parameters of hemostasis. It has been reported[11] that pregnancy is normally associated with increases in clotting and fibrinolytic activity and that in preeclampsia there appears to be an exaggeration of this pattern. We are unaware of any previous study that has applied recent advances in coagulation research to compare the roles of endothelial injury, clotting, and fibrinolysis in preeclampsia. We are also unaware of previous research with these techniques to systematically evaluate the usual effects of delivery or the specific effects of delivery for preeclampsia.

When interpreting these results, it is important to remember that blood levels reflect production, metabolism, and/or excretion. Although levels of the new markers are believed to be representative of their roles in hemostasis, other sources of variation could be involved. Fibronectin is produced in the liver and the vascular endothelium. Hepatic impairment or renal excretion could contribute to decreased levels of antithrombin III. Little is known about the metabolism and/or excretion of α_2-antiplasmin. Additional caution is warranted because of variability in the accuracy of the assays. Proteinuria, fibrin monomer, fibrin(ogen) split products, and D-dimer were qualitative or semiquantitative and much less accurate than fibronectin, fibrinogen, antithrombin III, and α_2-antiplasmin. Their qualitative or semiquantitative nature may also have reduced the efficiency of statistical analysis.

Nonetheless, the findings of this study integrate nicely into previously developed concepts of hemostasis (Fig. 1). Preeclampsia is accompanied by endothelial injury, clotting, and fibrinolysis, elements present in DIC. Vascular endothelial injury in preeclampsia could be caused by vasospasm or immune complexes. Endothelial damage may cause decreased prostacyclin production and activation of both clotting and fibrinolysis, resulting in the generation of thrombin and plasmin, respectively. Thrombin consumes antithrombin III and causes intravascular fibrin depositions. Plasmin consumes α_2-antiplasmin and converts fibrin and fibrinogen into fibrin(ogen) split products. Platelet activation leads to release of thromboxane A_2 and serotonin, which, along with low molecular weight fibrinolytic peptides, may induce further vasospasm and/or endothelial injury.[12] Elevated fibronectin may antagonize clotting by enhancing fibrinolysis, aiding in endothelial repair and solubilizing the fibrin monomer, thereby preventing the formation of a fibrin network.[13-14] Fibronectin also acts as an opsonin, allowing phagocytosis of formed blood clots by macrophages from microcirculation.[1] In the absence of clinical signs of DIC, increased fibronectin, accompanied by increased production of platelets and fibrinogen, appears to be adequate to compensate for increased consumption by clotting.

In summary, it appears that vascular endothelial injury plays a central role in the hemostatic changes associated with preeclampsia. This concept is further supported by the observation that it seemed to resolve 24 to 48 hours after delivery. This coincides with the rapid clinical improvement noted in the early puerperium and could contribute to recovery.

Elevated maternal serum α-fetoprotein levels and oligohydramnios: Poor prognosis for pregnancy outcome

Susanna N. Dyer, M.S.N., Barbara K. Burton, M.D., and Lewis H. Nelson, M.D.
Winston-Salem, North Carolina

The outcome of 21 pregnancies with elevated maternal serum α-fetoprotein levels associated with oligohydramnios was studied. Seven of the 21 pregnancies ended in spontaneous abortion or intrauterine fetal death before week 24 of pregnancy. Five patients experienced premature labor between 24 and 26 weeks of gestation; each fetus was either stillborn or died in the immediate neonatal period. Four patients were delivered of infants after 32 weeks of gestation; each infant was either stillborn or died in the immediate neonatal period. Four patients electively had their pregnancies terminated. One patient was delivered at term of a healthy, growth retarded male infant who on follow-up at age 17 months was developmentally normal. Only three cases were associated with a fetal defect. Patients should be counseled that, even in the absence of a demonstrable cause for diminished amniotic fluid on ultrasonography, raised maternal serum α-fetoprotein levels coupled with oligohydramnios seem to carry a poor prognosis. (AM J OBSTET GYNECOL 1987;157:336-9.)

Key words: Maternal serum α-fetoprotein, oligohydramnios

The association between raised concentrations of maternal serum α-fetoprotein and open fetal neural tube defects has been well documented.[1-3] Because more than 90% of all affected infants are born to women with no previous family history of a neural tube defect, the majority can be detected prenatally only by a testing program available to all pregnant women. An increasing number of women are being offered maternal serum α-fetoprotein screening as facilities capable of performing the test become widespread. It is now becoming apparent that elevated maternal serum α-fetoprotein levels even in the absence of a neural tube defect may indicate that a pregnancy is at high risk, and otherwise unexplained maternal serum α-fetoprotein elevations have been associated with an increased risk of spontaneous abortion and stillbirth,[1,4] low birthweight,[5,6] and other congenital anomalies.[7]

Previous reports have linked elevated maternal serum α-fetoprotein levels to second-trimester oligohydramnios. We describe a series of 21 patients found through diagnostic testing to have oligohydramnios; the tests were done after elevated maternal serum α-fetoprotein levels were discovered. Pregnancy outcomes for each case are discussed.

Methods

All patients studied were participants in the Screening Program for Neural Tube Defects administered by the Department of Pediatrics at the Bowman Gray School of Medicine, Winston-Salem, North Carolina. Initial maternal serum α-fetoprotein screening was generally performed at a gestational age of 16 to 18 weeks. Levels of ≥2.5 times the median were considered elevated, and further evaluation was rec-

Table I. Summary of patients with elevated maternal serum α-fetoprotein and oligohydramnios

Patient No.	*MSAFP MOM**	*Additional ultrasound findings*	*Pregnancy outcome*	*Autopsy results*	*Comments*
1	3.3/3.8		EPT	Normal	
2	8.5/10.0	IUGR	IUFD at 20 wk	Multiple placental infarcts	
3	3.0/4.0		IUFD at 20 wk	Amnionitis	
4	7.0/5.5	Fetal contractures	Spontaneous abortion at 20 wk	Multiple contractures	
5	2.8		IUFD at 24 wk	Normal	
6	9.4/12.0	Encephalocele	Stillborn at 32 wk	Not performed	Encephalocele, polydactyly, ambiguous genitalia on clinical examination
7	5.2/4.3		Premature delivery at 24 wk, died	Normal	
8	5.0/4.5		Spontaneous abortion at 20 wk	Not performed	No defects on clinical examination
9	5.1/4.5		EPT	Normal	
10	2.9/2.7		IUFD at 19 wk	Normal	
11	3.8/2.8	IUGR	Spontaneous abortion at 23 wk	Normal	
12	3.9/3.0	Kidney, bladder not visualized	Premature delivery at 32 wk, died	Not performed	Potter's syndrome on clinical examination
13	4.2/2.8	IUGR, encephalocele	Delivery at 40 wk, died	Encephalocele	Class A diabetes
14	2.5/3.8		Premature delivery at 25 wk, died	Not performed	No defects on clinical examination
15	2.8/2.6	FHR decelerations	Premature delivery at 37 wk, IUGR	Not performed	Doing well at age 17 mo
16	2.6/2.4		EPT	Normal	
17	4.0/5.3		Premature delivery at 24 wk, died	Not performed	No defects on clinical examination
18	2.5/2.0		Premature delivery at 26 wk, died	Not performed	No defects on clinical examination
19	3.6/5.1	Enlarged kidney and bladder	EPT	Posterior urethral valves, hydronephrosis	Potter facies
20	3.9		Spontaneous abortion at 22 wk	Not performed	No defects on clinical examination
21	3.6		Premature delivery at 32 wk, died	Not performed	Multiple contractures

MSAFP MOM = Maternal serum α-fetoprotein multiples of the median; EPT = elective pregnancy termination; IUGR = intrauterine growth retardation; IUFD = intrauterine fetal death; FHR = fetal heart rate.

*If patient had two samples assayed, both values are given.

ommended. Patients with an initial maternal serum α-fetoprotein elevation usually had a second sample quantitated at least 1 week later. After two consecutive elevations, women became candidates for ultrasound examination and possibly amniocentesis. Before these procedures, each patient received genetic counseling. Pregnancy outcome data were collected from delivery records or physician's offices on each patient who was considered a candidate for further testing. From June 1, 1978 to December 31, 1985, 34,932 patients participated in the screening program. Of these, 794 (2.3%) patients had elevated maternal serum α-fetoprotein levels on two separate occasions. As part of the screening protocol, each patient was recommended for consultative ultrasound to rule out a neural tube defect or other fetal defect. Of these, 21 patients were found to have oligohydramnios as defined by absence of amniotic fluid pockets >1 cm in depth. Ultrasound findings, pregnancy outcome, and autopsy data were reviewed for each case.

Results

Twenty-one cases of elevated maternal serum α-fetoprotein levels associated with oligohydramnios were identified during diagnostic testing after the discovery of elevated maternal serum α-fetoprotein levels. The findings are summarized in Table I. Of these, only one resulted in the birth of a healthy, viable infant. Seven pregnancies ended in spontaneous abortion or intrauterine fetal demise before 24 weeks of gestation.

Five pregnancies ended in premature labor and delivery between 24 to 26 weeks of gestation; each fetus was either stillborn or died in the immediate neonatal period. Four patients were delivered after 32 weeks of gestation; each infant was either stillborn or died in the immediate neonatal period. Four patients electively had their pregnancies terminated on the basis of counseling regarding the prognostic significance of oligohydramnios coupled with raised maternal serum α-fetoprotein levels. Autopsy results were available for 12 of the 21 patients, of which only three revealed fetal defects, including two cases of encephalocele and one case of urinary tract anomaly. Renal agenesis was suspected in another case; however, autopsy was not performed. An additional two fetuses had multiple joint contractures, presumably caused by intrauterine compression.

Case number 15 represents the only pregnancy in the series that resulted in the birth of a viable infant. Emergency cesarean section was performed at 37 weeks of gestation for acute preeclampsia and fetal heart rate decelerations. A 2000 gram male infant was delivered with a 1-minute Apgar score of 6 and a 5-minute Apgar score of 9. Hospitalization was complicated only by an elevated bilirubin level that spontaneously resolved. Aside from intrauterine growth retardation, no other anomalies were noted on physical examination. The infant was discharged after 10 days. On follow-up at age 17 months, he weighed 23 pounds (tenth percentile) and was developmentally normal.

Amniotic fluid levels of α-fetoprotein were available in four cases. Cases 1 and 15 had amniotic fluid α-fetoprotein levels below the mean, case 17 was slightly above the mean but within 2 SD, and case 2 was >5 SD above the mean. Karyotyping demonstrated a normal chromosome complement on all four samples of amniotic fluid.

Comment

Elevated levels of maternal serum α-fetoprotein have been associated with open fetal neural tube defects and other congenital anomalies, spontaneous abortion, fetal death, stillbirth, and low birth weight. Therefore, even in the absence of a neural tube defect, raised concentrations of maternal serum α-fetoprotein may serve as a predictor of a high-risk pregnancy.

Four previous reports have described a total of 18 cases of second-trimester oligohydramnios associated with elevated maternal serum α-fetoprotein levels. Balfour and Laurence[8] reported two infants who had renal agenesis, which was detected on postmortem examination. Both infants were delivered at 34 weeks of gestation and died in the immediate neonatal period. Seller and Child[9] described four cases, one of which resulted in the birth of an infant who was described as alive and progressing. Two patients chose to have their pregnancies terminated. No fetal defects were present in either fetus except for compression deformities observed in one. One patient prematurely was delivered of a male infant at 29 weeks of gestation with joint contractures, who died in the immediate neonatal period. Autopsy was not performed. Stirrat et al.[10] identified six cases, five of which ended in intrauterine or neonatal death. Of these, two were associated with extrauterine pregnancy, one with chronic leakage of amniotic fluid, and one with possible renal agenesis. One patient was delivered of a normal female infant at term. Koontz et al.[11] reported six additional cases, four of which were associated with urinary tract abnormalities. Five patients elected to have their pregnancies terminated; the sixth experienced intrauterine fetal death.

The present series brings to a total of 39 the reported cases of oligohydramnios associated with elevated maternal serum α-fetoprotein levels. Of these, four cases of renal agenesis have been identified, three cases of urinary tract obstruction, two cases of extrauterine pregnancy, and one case of chronic leakage of amniotic fluid. For these cases the cause of oligohydramnios is clear. For the remaining 29 cases (74%) the cause is unknown. Twenty-five of the 39 pregnancies (64%) ended in spontaneous abortion, intrauterine fetal death, stillbirth, or neonatal death. Eleven patients (28%) chose to terminate their pregnancies. Only three pregnancies (8%) have been associated with the birth of a viable infant.

It appears that in some cases oligohydramnios in itself is sufficient to explain elevated maternal serum α-fetoprotein levels. However, the relationship between oligohydramnios and elevated maternal serum α-fetoprotein levels is unclear. The mechanism by which open neural tube defects and other congenital anomalies elevate maternal serum α-fetoprotein levels has been reviewed by Brock[12] and appears to be linked to elevated levels of amniotic fluid α-fetoprotein. Increased amniotic fluid α-fetoprotein may occur when any open lesion such as a neural tube defect, ventral wall defect, or sacrococcygeal teratoma allows increased diffusion of α-fetoprotein from the fetal cerebrospinal fluid or serum. Another known cause of elevated maternal serum α-fetoprotein levels, congenital nephrosis of the Finnish type, produces fetal proteinuria with subsequent increased amniotic fluid α-fetoprotein. Finally, elevated amniotic fluid α-fetoprotein may be produced by altered amniotic fluid protein turnover from decreased fetal swallowing, as in duodenal or esophageal obstruction.

In contrast, it does not appear that elevated maternal serum α-fetoprotein levels found in pregnancies affected with oligohydramnios can be linked to elevated amniotic fluid α-fetoprotein, since in three of the four

cases in our series in which amniotic fluid α-fetoprotein was measured, this level was normal. Because it appears that urination is the principle route by which α-fetoprotein normally reaches amniotic fluid, one might expect urinary tract anomalies to result in low levels of amniotic fluid α-fetoprotein. Therefore, for the eight reported cases of urinary tract anomalies, elevated maternal serum α-fetoprotein levels may appear to be paradoxical. Amniotic fluid measurements were not available for any of these cases. Koontz et al.[11] speculated that elevated fetal serum α-fetoprotein levels may result from the inability of the fetus to excrete α-fetoprotein when urinary tract anomalies are present. Consequently, elevated levels of maternal serum α-fetoprotein may result from the greatly increased fetal-maternal concentration gradient across the placental membrane. For the other cases of oligohydramnios, adverse events might occur early in pregnancy, which simultaneously result in oligohydramnios and elevation of maternal serum α-fetoprotein levels, perhaps through some alteration of placental structure or function. Therefore, although no causal relationship may be present between oligohydramnios and elevated maternal serum α-fetoprotein levels, a common origin may exist for both.

Patients should be counseled that elevated maternal serum α-fetoprotein levels coupled with oligohydramnios appear to carry a poor prognosis for the pregnancy. Even in the absence of a demonstrable fetal defect on ultrasonography, the likelihood of a normal outcome remains low.

We gratefully acknowledge the support and efforts of the participating physicians in western North Carolina, without whom this project would not have been possible.

Mycotic aneurysms in pregnancy

Guy M. Boike, M.D., Norman Gove, M.D., Mitchell P. Dombrowski, M.D., Gunter Deppe, M.D., and Robert J. Sokol, M.D.
Detroit, Michigan

The presentation, management, and outcome of three cases of femoral artery mycotic aneurysm in pregnancy are described. All resulted from illicit intravenous drug use. While the literature dealing with drug abuse in pregnancy is large, this specific problem has received little attention. Comparison of these cases to a large reported series of nonpregnant patients with mycotic aneurysms from our institution demonstrates that pregnancy does not alter the natural course of this condition. The presence of a mycotic aneurysm in pregnancy does, however, appear to lead to significant maternal and fetal morbidity. Guidelines for diagnosis and management are discussed. (AM J OBSTET GYNECOL 1987;157:340-1.)

Key words: Pregnancy, aneurysms, intravenous drug abuse

Arterial aneurysms are an infrequent complication of pregnancy. The term mycotic aneurysm was first coined by Osler in 1885 to describe aortic aneurysms resembling "fungal growths" in a man with endocarditis. The potentially catastrophic consequences of aneurysmal rupture and the accompanying infectious morbidity emphasize the need for early diagnosis and appropriate management. The purpose of this report is to communicate our experience with three intravenous drug abusers whose pregnancies were complicated by femoral artery mycotic aneurysms.

Case reports

Case 1. A 33-year-old woman, gravida 2, para 1, abortions 0, was admitted at 20 weeks' gestation for bleeding from an injection site in the groin. A pulsatile right groin mass with a bruit was present and an arteriogram demonstrated a 2 cm aneurysm of the deep femoral artery. Ligation of the superficial, common, and deep femoral artery was performed. Cultures from the aneurysm grew nafcillin-resistant *Staphylococcus aureus* and *Klebsiella pneumoniae*. Estimated operative blood loss was 700 ml and a transfusion of 2 units of blood was required. At 25 weeks' gestation, ischemic changes and purulent drainage from the wound necessitated a right above-the-knee amputation. The patient remained hospitalized without further complications. At term, an elective induction of labor resulted in the vaginal delivery of a healthy, appropriate for gestational age infant. After an uncomplicated postpartum course, both mother and infant were discharged.

Reprint requests: Guy M. Boike, M.D., Hutzel Hospital, Department of Obstetrics and Gynecology, 4707 St. Antoine, Detroit, MI 48201.

Case 2. A 34-year-old woman, gravida 6, para 3, abortions 2, was admitted at 34 weeks' gestation with a draining right groin abscess and a swollen, painful left thigh. A pulsatile left groin mass with a bruit was present and an arteriogram confirmed a 4 cm left femoral aneurysm. The draining right groin abscess grew nafcillin-resistant *S. aureus*. Shortly after admission, the patient experienced spontaneous rupture of the membranes accompanied by labor and was delivered vaginally of a preterm, small for gestational age infant that experienced mild respiratory distress. After delivery the patient underwent ligation of the left common and superficial femoral arteries without complication. The patient remained hospitalized for 25 days and was maintained on intravenous vancomycin while the wound healed.

Case 3. A 34-year-old woman, gravida 3, para 2, was admitted at 33 weeks' gestation with a swollen, painful left thigh. The patient stated that a pulsatile left groin mass had been present for 1 year. An arteriogram revealed a 9.5 cm left femoral aneurysm. In an effort to avoid operation during pregnancy and because of the relative proximity to term, the patient was managed conservatively while awaiting fetal maturity. At term, an elective cesarean delivery was performed because of a breech-vertex twin presentation and to avoid the risk of aneurysmal rupture during labor. The patient was delivered of otherwise healthy discordant twins (twin A, appropriate for gestational age; twin B, small for gestational age). After delivery the patient did well but refused ligation of the aneurysm and signed out against medical advice on the fifth postoperative day.

Comment

Care of the pregnant patient who engages in intravenous drug abuse is complicated by many obstetric and medical problems. All of our patients received no prenatal care, had uncertain gestational dates, and experienced complications from intravenous drug abuse. Previous reports of mycotic aneurysms in pregnancy are limited, possibly reflecting underreporting. Dir-

ghani and Ansari[1] reported a case of a ruptured right external iliac artery aneurysm secondary to drug abuse in a pregnant patient. This led to an intrauterine fetal death and significant maternal morbidity.

A series of 50 nonpregnant patients with mycotic aneurysms has been reported from our institution.[2] Local pain, swelling, bleeding, and symptoms of vascular insufficiency were the most common presenting complaints. A pulsatile, indurated mass with an associated bruit was present in nearly all cases, with the femoral artery being the most frequently involved site. Approximately 80% of the patients were adequately treated with simple ligation and excision, but the remaining 20% required bypass or amputation. Resistant *S. aureus* was isolated from more than three quarters of the cases.

A thorough history and physical examination are necessary in patients who abuse drugs intravenously, with special attention given to complaints referred to injection sites and extremities. Careful palpation for fluctuance or pulsations and auscultation for bruits is essential for the diagnosis of an underlying abscess or aneurysm. Arteriograms should be liberally used for confirmation. Operation for this condition during pregnancy presents potential fetal risks including anesthetic complications, hypotension from supine positioning, and decreased placental perfusion from operative blood loss. The delay in surgical treatment may result in aneurysmal rupture with maternal hypotension, decreased placental perfusion, and possibly fetal death.[1] The effect of second-stage valsalva maneuvers may increase the risk of aneurysmal rupture, although there is little evidence to confirm this. At all gestational ages, the risk of operation to the undelivered fetus must be weighed against delaying definitive treatment.

It is difficult to formulate a management scheme on the basis of this limited experience; however, the following guidelines would appear appropriate: (1) Leaking or expanding aneurysms require immediate operation irrespective of gestational age. If viable, the fetus should be monitored during operation and the attending obstetrician prepared to perform a cesarean delivery for fetal indications. (2) Aneurysms diagnosed during the first and second trimesters should be surgically treated. (3) Near term, attempts at conservative management awaiting fetal maturity should be considered, with delivery prior to operation. (4) Careful attention to bacterial isolates and resistance patterns is necessary to optimize antibiotic therapy. With early diagnosis and intensive surgical-obstetric management, the excessive morbidity of this condition in pregnancy may be minimized.

We wish to acknowledge the expert technical assistance of Suellen J. Pence.

A screening test (GBS-Test) for urogenital carriage of group B streptococci

Karen Christensen, M.D., Ph.D., and Poul Christensen, M.D., Ph.D.
Lund, Sweden

A commercial kit for the detection of group B streptococci (GBS-Test) is described. The test is based on orange pigment production after 2 days' incubation at 37° C. It showed a 100% specificity and a sensitivity superior to that of a conventional selective broth method. (Am J Obstet Gynecol 1987;157:341-2.)

Key words: Group B streptococci, pregnancy, screening

From the Fdeon Science Park.
Received for publication July 22, 1986; revised February 4, 1987; accepted March 12, 1987.
Reprint requests: Dr. Karen K. Christensen, Fdeon Science Park, S-22370 Lund, Sweden.

Recently, a successful prevention program for the majority of early-onset group B streptococcal infections was described, based on screening during pregnancy.[1] The present paper describes a new commercial kit

Table I. Comparison of a conventional selective method and the GBS-Test for detection of group B streptococci in the urethra, cervix, and rectum

Site of collection of specimen	*No. of specimens containing group B streptococci per No. collected*	*Conventional selective method*		*GBS-Test*			
		No. of tests positive for group B streptococci	*Sensitivity (%)*	*No. of tests positive*		*Sensitivity (%)*	
				Day 1	*Day 2*	*Day 1*	*Day 2*
Urethra	58/200	53	91	57	58	98	100
Cervix	53/200	46	87	48	49	91	92
Rectum	29/100	25	86	21	25	72	86
All specimens	140/500	124	89	126	132	90	94

(GBS-Test*) which is suitable for the detection of group B streptococci during pregnancy.

The test consists of a tube containing 1.5 ml of broth. Each specimen to be investigated for group B streptococci was obtained with a cotton-tipped swab, which was then whisked out in the broth. The tube was capped and incubated for 2 days at 37° C. On days 1 and 2, tubes were inspected for orange pigmentation, indicating the presence of group B streptococci.

With this technique, 500 urogenital specimens were evaluated, 200 from the urethra, 200 from the cervix, and 100 from the rectum. All specimens were transported in Stuart medium within 24 hours of collection. Each specimen was whisked out in 1 ml of Todd-Hewitt broth at a temperature of 4° to 8° C. Two sterile cotton swabs were then dipped simultaneously in the broth; one of them was used for selective broth medium isolation of group B streptococci, and the other was used for detection of these bacteria with the GBS-Test.

When a GBS-Test was positive but no β-hemolytic streptococci had been detected on the blood agar plate, new attempts were made to isolate the bacteria from the Todd-Hewitt broth, by use of the selective method. The results of the "second look" were not included in the data given for the selective method (Table I).

The sensitivity of the conventional method was 91% for the urethra, 87% for the cervix, and 86% for the rectum (Table I). The respective figures for the GBS-Test were 100%, 92%, and 86% after 2 days of incubation. No false positive results were recorded with the GBS-Test (specificity = 100%).

All of 14 group B streptococcal strains isolated from cerebrospinal fluid or blood of newborn infants gave positive results with the GBS-Test, 13 after 24 hours' incubation and the fourteenth strain after 42 hours' incubation.

The data thus demonstrated that the GBS-Test was at least as reliable as a conventional selective method used for detection of group B streptococci at bacteriologic laboratories.

Although it does not appear to be quicker than conventional methods, the test permits diagnosis of group B streptococci at the doctor's office. The simple handling and easy reading of the test and a cost below 6 dollars for two tubes (that is, one screening occasion) has radically changed the cost-benefit ratio in favor of routine screening for group B streptococci during pregnancy. When this test is combined with prophylactic antibiotics in selected patients at risk,[1] we now have access to an instrument that can prevent a substantial part of early-onset group B streptococcal infections in newborn infants.

*Patent pending.

Fetal growth retardation as a complication of pregnancy in patients with neurofibromatosis

Isaac Blickstein, M.D., and Moshe Lancet, M.D.
Rehovot, Israel

Neurofibromatosis adversely affects reproductive performance. Fetal growth retardation as a complication of pregnancy in patients with neurofibromatosis had not been widely documented. The present cases suggest that pregnant patients with neurofibromatosis may have an increased risk for growth-retarded babies. (AM J OBSTET GYNECOL 1987;157:343.)

Key words: Neurofibromatosis, pregnancy complications, fetal growth retardation

Von Recklinghausen's neurofibromatosis is associated with many pregnancy complications. The pregnant state may, in turn, aggravate the disease to the point of life-threatening situations. Belton et al.[1] reported what they assumed to be the first case of intrauterine growth retardation in association with neurofibromatosis in pregnancy. The present cases document five additional growth-retarded babies born to two patients with neurofibromatosis.

Case reports

Case 1. S. A., a 30-year-old gravida 2, para 1, was admitted at 38 weeks' gestation in active labor. Mild neurofibromatosis was diagnosed at her previous delivery in 1984 by the attending obstetrician. Both pregnancies were achieved after ovulation induction with clomiphene, human menopausal gonadotropin and human chorionic gonadotropin, and bromocriptine. They were unremarkable with respect to weight gain, hemoglobin levels, and blood pressure. The first baby was growth retarded (2400 gm at 39 weeks' gestation) and had inherited his mother's disease. The second one was born at 38 weeks' gestation and was severely growth retarded (1820 gm). The placentas were with no stigmata of neurofibromatosis, relatively small, with areas of infarction.

Case 2. I. R., a 23-year-old gravida 3, para 2, was admitted at 35 weeks' gestation. She had mild neurofibromatosis since childhood. She previously had a 1500 gm growth-retarded baby at 35 weeks and a second one at 39 weeks weighing 2250 gm.

Her three pregnancies were unremarkable with respect to the aforementioned factors. The third pregnancy ended by a cesarean section because of preterm rupture of the membranes and fetal distress. A 1850 gm growth-retarded baby was born. The placenta was relatively small but otherwise normal. The two older children do not have signs of neurofibromatosis, nor have any such signs been found in the newborn infant.

Comment

Possible explanations for intrauterine growth retardation associated with neurofibromatosis include: (1) Vascular changes characteristic of neurofibromatosis may lead to insufficient blood supply to the gravid uterus, (2) a rapidly growing neurofibromatic pelvic tumor may displace the uterus and compress the major blood vessels, and (3) nontoxemic hypertension is thought to be an invariable feature of pregnant patients with neurofibromatosis.

Belton et al.[1] reported a case of fetal growth retardation and oligohydramnios in association with neurofibromatosis. What they claimed as the first reported case had been criticized as coincidental.[2] Our cases suggest that fetal growth might be impaired by the disease process of neurofibromatosis. Since we could not single out other causes for intrauterine growth retardation in our patients, neurofibromatosis and its adverse effects on the uteroplacental unit seem to be most likely.

Neurofibromatosis affects many organs and systems, and thus a multifactorial etiology for intrauterine growth retardation seems probable. Further observations may disclose the actual magnitude of this complication in the relatively infrequent combination of pregnancy and neurofibromatosis.

γ-Glutamyl transferase and mean cell volume reveal maternal alcohol abuse and fetal alcohol effects

Olavi Ylikorkala, M.D., Ph.D., Ulf-Håkan Stenman, M.D., Ph.D., and Erja Halmesmäki, M.D.

Helsinki, Finland

Serial measurements of γ-glutamyl transferase and mean cell volume were done in 85 pregnant alcohol abusers (320 samples). These included 26 moderate drinkers, 30 heavy drinkers, and 29 alcoholic women. Studies of 28 pregnant women who denied the use of alcohol (138 samples) showed that pregnancy itself had no effect on γ-glutamyl transferase and mean cell volume. However, γ-glutamyl transferase was increased in 14.9%, 31.7% and 59.1% of the samples collected from moderate drinkers, heavy drinkers, and alcoholic women, respectively, and likewise mean cell volume was elevated in 10.8%, 17.2%, and 40.2%, respectively. Either γ-glutamyl transferase or mean cell volume was high or both were high in 27.1% of the moderate drinkers, in 38.3% of the heavy drinkers, and in 76.3% of the alcoholic women. Fetal alcohol effects developed in 42 cases. Increased γ-glutamyl transferase predicted fetal alcohol effects in 61.5%, with a relative risk of 2.51. Elevated mean cell volume predicted fetal alcohol effects in 40.9%, with a relative risk of 2.40. These results suggest that the assay of γ-glutamyl transferase and mean cell volume can be valuable in monitoring pregnant women with recognized or suspected alcohol abuse. (AM J OBSTET GYNECOL 1987;157:344-8.)

Key words: Alcohol abuse in pregnancy, fetal alcohol effects, γ-glutamyl transferase, mean cell volume

The measurements of serum γ-glutamyl transferase activity and mean cell volume are the best established tests for the detection of alcohol abuse in women who are not pregnant.[1-6] Excessive alcohol consumed during pregnancy is one of the most common teratogens known today.[7, 8] This may be one reason pregnant women often are most reluctant to admit their actual alcohol consumption.

Objective biochemical tests are therefore needed to reveal alcohol use during pregnancy. Because pregnancy may affect the responses of these markers to alcohol intake, data on γ-glutamyl transferase and mean cell volume in women who use alcohol but are not pregnant[1-6] cannot be interpolated to pregnant subjects. Therefore we assessed the value of γ-glutamyl transferase and mean cell volume in the detection of alcohol abuse and fetal alcohol effects during pregnancy.

Material and methods

From April 1983, staff members of antenatal clinics in Helsinki and its suburbs were trained to recognize alcohol abuse (history of previous use, social reports, previous treatments, drunkenness at follow-up). To the end of 1985, 85 patients with recognized alcohol problems had been identified. They were admitted to a special outpatient university clinic for pregnant problem drinkers. The patients were interviewed about their alcohol use at registration and were counseled to refrain from alcohol use or, if that was impossible, to limit its use as much as possible. The patients were scheduled to visit the department at 2- to 4-week intervals, when a detailed history on alcohol use since the preceding visit was taken and further counseling and support were given. The patients were advised to use iron supplements, but no folic acid supplementation was used.

Of 85 patients, 29 women has consumed two to 20 "drinks" daily during early pregnancy. They were regarded as alcoholic because their history of alcohol abuse was long (up to 20 years) and they had several alcohol-related social problems. Thirty women who had one to 10 "drinks" daily were classified as heavy drinkers because, although they drank heavily, they lacked other features typical for alcoholism. Twenty-six women consumed alcohol periodically (mostly during weekends), up to 10 "drinks" daily, and they were clas-

sified as moderate drinkers (Table I). Sixty-six patients (78%) also smoked. Otherwise the women were apparently healthy and had no evidence of liver disease. Fifty-five patients (65%) reported that they had reduced their alcohol consumption since their registration (Halmesmäki E, unpublished data).

Infants born to these 85 women were thoroughly studied at ages 5 days (n = 85), 4 months (n = 72), 6 months (n = 72), and 12 months (n = 47) by pediatricians. The diagnosis of fetal alcohol effects required one of the following criteria: growth retardation (less than the tenth normal percentile); distinctive facial characteristics (low nasal bridge, short nose, short palpebral fissures, indistinct philtrum, thin upper lip); neurological aberrations; and developmental delay. Twenty-two such infants were born. In addition, 20 infants fulfilled three of the criteria (growth retardation, distinctive facial features, neurological aberrations), and they were regarded as suffering from a complete "fetal alcohol syndrome."[7, 8] Thus alcohol-induced fetal damage was observed in 42 of 85 infants (49%).

Twenty-eight healthy women who denied the use of alcohol had follow-up throughout pregnancy as a control group (Table I). They all were advised to use iron supplementation starting at 12 to 16 weeks of pregnancy, but no folic acid was prescribed. Six of them (21%) smoked. The pregnancies were uneventful, and the infants were healthy.

Venous blood samples collected at each visit from the patients (on average 3.7 samples per patient) and controls (on average 4.8 samples per control) were assayed for γ-glutamyl transferase with a Hitachi 705 E analyzer (Hitachi, Tokyo, Japan) (based on Scandinavian recommendation[9]). The mean cell volume was determined with a Coulter S7 cell counter (Coulter Electronics, Hialeah, Florida).

Individual values of γ-glutamyl transferase and mean cell volume on any occasion were considered separately in different drinking groups. The relationship between degree of alcohol abuse and occurrence of fetal alcohol effects was interpreted as follows: true positive (TP) (marker high, abuse positive, fetal alcohol effects positive), false positive (FP) (marker high, abuse negative, fetal alcohol effects negative), true negative (TN) (marker normal, abuse negative, fetal alcohol effects negative), and false negative (FN) (marker normal, abuse positive, fetal alcohol effects positive). Sensitivity of the indices was TP/(TP + FN), specificity TN/(TN + FP), predictive value TP/(TP + FP), and relative risk factor, the ratio of TP/(TP + FP) to FN/(FN + TN). The significances of the differences were tested by binomial t test.

Results

The γ-glutamyl transferase (range 3 to 65 U/L) and mean cell volume (range 85 to 98 fl) in the control women did not change with advancing gestation.

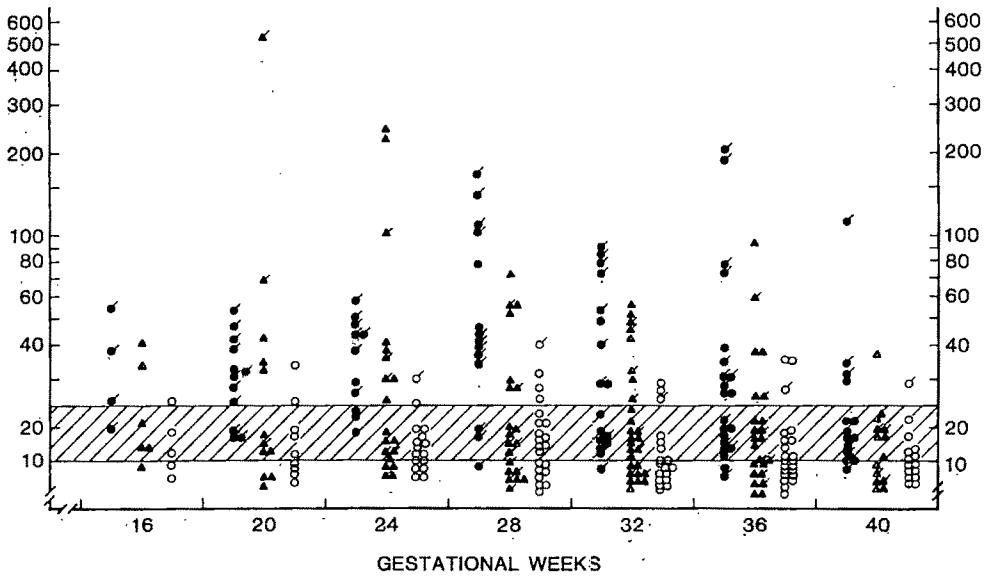

Fig. 1. Individual γ-glutamyl transferase activities (units per liter) in pregnant female alcohol abusers. The *shaded area* represents the mean ± 2 SD in 28 abstinent healthy pregnant women who had follow-up throughout pregnancy. Alcoholic women (●); heavy drinkers (▲); moderate drinkers (○). Note the logarithmic scale for γ-glutamyl transferase. ◐, ◭, and ♂ indicate values in women who gave birth to infants with alcohol effects.

Table III. Efficacy of combined use of γ-glutamyl transferase and mean cell volume to reveal alcohol abuse during pregnancy

	Moderate drinkers (%)	*Heavy drinkers (%)*	*Alcoholic women (%)*	*All drinkers (%)*
Increased γ-glutamyl transferase, normal mean cell volume	15.9	13.3	30.1	19.1
Normal γ-glutamyl transferase, increased mean cell volume	12.1	6.7	17.2	11.6
Increased γ-glutamyl transferase and/or mean cell volume	27.1	38.3	76.3	45.6

Table IV. Sensitivity, specificity, predictive value, and relative risk of increased γ-glutamyl transferase and mean cell volume in predicting fetal alcohol effect

	γ-Glutamyl transferase	*Mean cell volume*	*Significance*
Sensitivity (%)	61.5	40.9	$p < 0.001$
Specificity (%)	78.5	87.9	$p < 0.01$
Predictive value (%)	59.3	65.3	NS
Relative risk	2.51	2.40	NS

NS = Not significant.

Therefore the mean + 2 SD was taken as the upper reference limit. These were 24.5 U/L for γ-glutamyl transferase and 96.6 fl for mean cell volume (Figs. 1 and 2). A total of 94.8% of the γ-glutamyl transferase values (128 of 135) and 95.6% of the mean cell volume values (132 of 138) in the control women were within the reference range.

Maternal alcohol abuse directly correlated with increased γ-glutamyl transferase and mean cell volume values (Figs. 1 and 2). Both markers revealed maternal alcohol abuse in relation to its severity, but the γ-glutamyl transferase was more sensitive (Table II). Increases in γ-glutamyl transferase and mean cell volume did not always coincide, and therefore the combined use of the markers resulted in the greatest efficacy in revealing alcohol abuse (Table III).

The rate of increased γ-glutamyl transferase and mean cell volume values decreased from 28 weeks of gestation onward (Fig. 3). A high γ-glutamyl transferase or large mean cell volume predicted the development of fetal alcohol effects (Figs. 1 and 2, Table IV). γ-Glutamyl transferase was more sensitive but less specific than mean cell volume, whereas predictive values and relative risks were fairly similar (Table III).

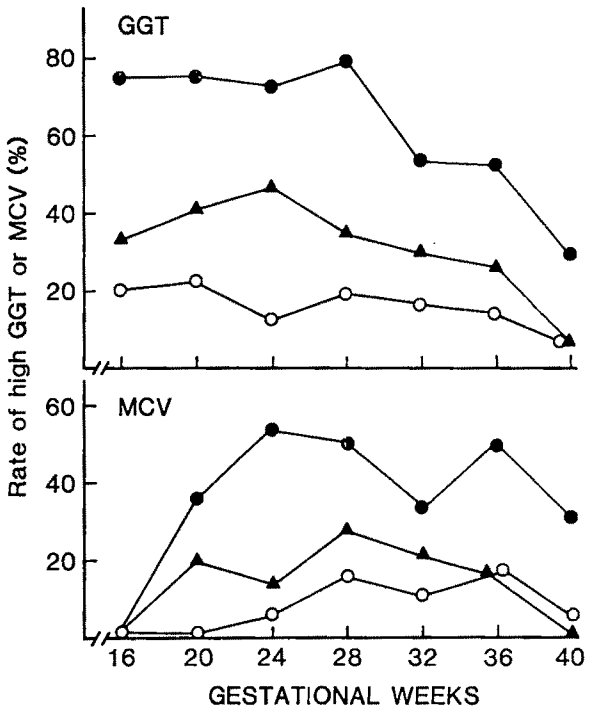

Fig. 3. The rate of high γ-glutamyl transferase *(GGT)* and mean cell volume *(MCV)* in pregnant alcoholics (●) and in women with heavy (▲) or moderate (○) alcohol use in relation to gestational age.

Comment

Approximately 40% of pregnant alcoholic women but only one of 600 to 700 unselected parturients give birth to infants with complete fetal alcohol syndrome; milder forms of fetal alcohol effects are at least twice as common.[8] An excessive amount of alcohol is the most common known teratogen today. The only way to prevent fetal alcohol effects is to identify problem drinkers before pregnancy or as soon as possible during pregnancy, when the fetus may not yet be damaged, and to counsel these women to refrain from alcohol use.

We assessed the usefulness of γ-glutamyl transferase and mean cell volume in revealing alcohol abuse in pregnant women who were known to have alcohol problems and who could have follow-up throughout pregnancy. Forty-two of the women (49%) had drunk so much before entering our project or drank so heavily after registration that their fetuses were damaged. From such cases we could also evaluate the efficacy of γ-glutamyl transferase and mean cell volume tests in predicting fetal alcohol effects.

Long-term excessive consumption of alcohol leads to increased serum γ-glutamyl transferase, either by direct damage to the liver cell or by the induction of microsomal enzymes in the absence of overt damage; it leads to increased mean cell volume by the direct action of ethanol on the developing erythroblasts.[1-6] In contrast to identification of blood ethanol level, these changes can remain detectable for weeks. Alcohol abuse often remains unrecognized during pregnancy because women drinkers seem to be able to refrain from drinking for a couple of days before follow-up visits at their prenatal centers. This was also seen in the present study, since only 7% of the blood samples contained detectable levels of ethanol (Halmesmäki E, unpublished data).

The γ-glutamyl transferase level is high in two thirds of pregnant alcoholic women and one third of pregnant heavy drinkers. This fits well with the data on nonpregnant alcoholic women of whom 50% to 80% have

increased γ-glutamyl transferase levels.[3, 5, 6] One study group has assessed the value of γ-glutamyl transferase as a screening method for alcohol consumption during the first trimester of pregnancy.[10] In this study 13% of 669 women had consumed more than 30 gm of ethanol per day, and two produced infants with fetal alcohol effects.[10] Only 25% of these women had an increased γ-glutamyl transferase value.[10] It is likely that the average alcohol consumption of our patients was higher than that in the previous study,[10] since much higher rates of fetal alcohol effects and increased serum levels of γ-glutamyl transferase were found in our study.

The mean cell volume test is a less sensitive marker than γ-glutamyl transferase for detection of alcohol abuse during pregnancy, as it also is in nonpregnant subjects.[3, 5, 6] This difference is at least partly explained by the long life span of erythrocytes. Alcohol-induced biochemical change that causes macrocytosis is fully reflected in the mean cell volume value only after 120 days. For this reason mean cell volume may reflect better the long-term alcohol effects, whereas γ-glutamyl transferase responds more rapidly. An increased mean cell volume also was found more often with advancing gestation (Fig. 3). This may suggest that in pregnancies complicated with alcohol abuse, the sensitivity of erythroblasts to ethanol increases. Folic acid deficiency and/or smoking may be factors in this regard because they both may lead to increased mean cell volume.

No prenatal diagnostic methods exist for fetal alcohol effects. An elevated γ-glutamyl transferase level predicts fetal alcohol effects relatively well, whereas the sensitivity of mean cell volume is low but the specificity high. In predicting fetal alcohol effects the sensitivity and specificity of these rather simple laboratory methods compare favorably with those of low levels of α-fetoprotein and β_1-glycoprotein in maternal serum.[11] Although prenatal measurement of γ-glutamyl transferase and mean cell volume can be used to evaluate the risk of fetal alcohol effects, we do not yet have any effective preventive treatments for subjects who cannot stop drinking.

The responses of γ-glutamyl transferase and mean cell volume to alcohol were not uniform, and mean cell volume was increased in 6.7% to 17.2% of the samples with normal γ-glutamyl transferase levels. A combined use of γ-glutamyl transferase and mean cell volume thus revealed the maternal alcohol abuse better than did either test alone. Furthermore, although the majority of patients (65%) reported a reduced alcohol use during follow-up visits (Halmesmäki E, unpublished data), γ-glutamyl transferase values remained high to 32 weeks of pregnancy, and high mean cell volume values became more frequent. This may imply that contrary to their own reports, the patients failed to reduce their alcohol use (and/or smoking) until the last 6 to 8 weeks of pregnancy. γ-Glutamyl transferase and mean cell volume measurements may therefore be used as objective indices of the efficacy of alcohol counseling in pregnant problem drinkers.

In conclusion, increased γ-glutamyl transferase and/or mean cell volume reveal maternal alcohol abuse during pregnancy so reliably that these markers should be determined routinely, at least in women with recognized or suspected alcohol problems.

Progesterone synthesis by human amnion, chorion, and decidua at term

B. F. Mitchell, M.D., J. R. G. Challis, Ph.D., D.Sc., and L. Lukash, B.Sc.
London, Ontario, Canada

We investigated the ability of human fetal membranes to produce progesterone from a variety of substrates. Chorion is more active than decidua, and amnion produces little progesterone. Cholesterol or low-density lipoprotein cholesterol was not used as a substrate. Chorion used pregnenolone, pregnenolone sulfate, and 20α-dihydroprogesterone for progesterone synthesis. Decidua also used these three substrates but produced significantly less progesterone than chorion. Amnion used only 20α-dihydroprogesterone as a substrate. Exogenous human chorionic gonadotropin or gonadotropin-releasing hormone or its analogues did not influence progesterone production by any of the tissues. There were several significant changes in substrate usage for progesterone synthesis by the tissues around the time of the onset of labor. Tissue concentrations of progesterone are approximately 4 ng/mg protein, and it appears that local production rates could completely account for this. These data are compatible with the hypothesis that local regulatory mechanisms may determine progesterone concentrations in fetal membrane tissues and that important changes may occur around the time of the onset of parturition. (AM J OBSTET GYNECOL 1987;157:349-53.)

Key words: Progesterone, amnion, chorion, decidua

Several studies in recent years have demonstrated the ability of human fetal membranes to synthesize and metabolize progesterone.[1-5] We have hypothesized that local paracrine events may regulate tissue progesterone concentrations within the fetal membranes, and these in turn may modify myometrial contractility. Investigations in our laboratory have shown that pregnenolone can be used as a substrate for progesterone synthesis and that chorion is the most active tissue in this regard.[1,2] We also demonstrated that other steroid hormones can modify this reaction.[1,3] The studies presented here extend our observations into progesterone synthesis by human amnion, chorion, and decidua.

It is well established that human chorionic gonadotropin (hCG) stimulates progesterone production in luteal cells. Recent studies[6,7] have demonstrated an effect of gonadotropin-releasing hormones (GnRH) on placental progesterone production. Thus we have performed studies to investigate the potential regulation of pregnenolone conversion to progesterone by hCG and GnRH or its analogues.

From the Research Institute, St. Joseph's Hospital, Department of Obstetrics and Gynaecology, University of Western Ontario.
Presented in part at the Thirty-third Annual Meeting of the Society for Gynecologic Investigation, Toronto, Ontario, Canada, March 19-22, 1986.
Received for publication August 28, 1986; revised February 9, 1987; accepted March 5, 1987.
Reprint requests: B. F. Mitchell, M.D., Department of Obstetrics and Gynecology, University of Alberta, Edmonton, Alberta, Canada T6G 2R7.

Pregnenolone may be derived from two potential sources. It is well established that many tissues that secrete steroids use cholesterol associated with low-density lipoprotein as a source of substrate. Alternatively, pregnenolone may be produced from the hydrolysis of the high concentrations of pregnenolone sulfate, which are present in late human pregnancy.[8] In placental tissue progesterone also may be synthesized by conversion of one of its own metabolites, 20α-dihydroprogesterone.[9] We have investigated the ability of human fetal membrane tissues to use these various substrates for synthesis of progesterone.

If we are to hypothesize that local progesterone production within the fetal membranes may be an important regulator of local tissue progesterone concentrations, we must gain information concerning the amount of progesterone necessary to suffice local requirements. Thus we have measured endogenous progesterone concentrations within the amnion, chorion, and decidua at term.

Material and methods

Fetal membrane tissues were obtained immediately after delivery from women with uncomplicated pregnancies who gave birth at 38 to 42 weeks of gestation. Delivery occurred either after spontaneous onset of labor and vaginal delivery or by elective repeat cesarean section before the onset of labor. No oxytocics, narcotics, anesthetic agents, or antibiotics were used before delivery. Continuous epidural analgesia was provided for cesarean sections and most vaginal deliveries.

Table I. Effect of hCG and GnRH on progesterone synthesis from pregnenolone by dispersed cells

Substrate	*Chorion (n = 8)*	*Decidua (n = 4)*
Control	1.0 ± 0.5	0.2 ± 0.1
Pregnenolone (1 μg)	27.3 ± 4.2	6.6 ± 2.1
Pregnenolone + hCG (10 IU)	31.2 ± 7.0	5.3 ± 1.8
Pregnenolone + GnRH (10 ng)	24.5 ± 5.1	4.2 ± 1.3

Values are mean ± SEM (nanograms of progesterone produced per 10^5 cells per 4-hour incubation period).

Table II. Use of pregnenolone and cholesterol for progesterone synthesis by tissue explants (N = 6 patients)

Substrate	*Chorion*	*Decidua*
Control	31.5 ± 4.8	17.5 ± 3.2
Pregnenolone (1 μg)	1057 ± 213	673 ± 150
Cholesterol (μg)	30.7 ± 5.9	21.9 ± 5.4
Low-density lipoprotein cholesterol (5 μg)	27.6 ± 6.9	18.6 ± 4.7
Low-density lipoprotein cholesterol (50 μg)	36.6 ± 7.0	20.5 ± 3.8

Values are mean ± SEM (nanograms of progesterone produced per milligram of tissue protein per 24-hour incubation period).

The tissues were rinsed immediately in cold saline solution. The amnion was bluntly dissected from the choriodecidua and the decidua gently separated from the chorion. The tissues were either (1) minced and dispersed with 0.05% collagenase, as described previously,[1] or (2) cut into explants and incubated in minimal essential medium.[2] In both systems, two to four replicates were performed for each incubation. The dispersed cell incubations were conducted for 4 hours in room air at 37° C on a metabolic shaker. Each tube contained 75,000 to 200,000 cells (excluding red blood cells), and results were expressed as the amount of progesterone produced per 10^5 cells/4 hours. Cells were counted with a hemocytometer, and viability was assessed by trypan blue exclusion, which was always >90%. The tissue explants were incubated for 4 or 24 hours in 95% oxygen and 5% carbon dioxide at 37° C. Results were expressed as progesterone produced per milligram of tissue protein per 4 or 24 hours. Protein was estimated with the method of Lowry et al.[10]

To measure endogenous progesterone concentrations, tissue samples were obtained from sites near (within 2 cm) the edge of the placental disc, at the edge of the membranes most distant from the placenta, or an area midway between these two. The tissues were homogenized with a Brinkmann Polytron (Brinkmann Instruments, Inc., Westbury, New York). The crude homogenates were extracted twice with 5 volumes of diethyl ether. Extraction recovery was calculated with parallel tubes with the addition of radiolabelled progesterone. Extraction efficiency was >90%. The ether was evaporated and endogenous progesterone measured by radioimmunoassay.

All steroids were obtained from Steraloids Inc., Wilton, New Hampshire. The pregnenolone and 20α-dihydroprogesterone were recrystallized before use. The pregnenolone sulfate was extracted with ether before use to remove any spontaneously hydrolyzed product. The low-density lipoprotein cholesterol was prepared from human plasma by ultracentrifugation and was generously supplied by Dr. Murray Huff of the Department of Internal Medicine, University Hospital, London, Ontario, Canada. The GnRH and analogues were the generous gifts of Drs. E. R. Plunkett, Kalyan Sundaram and C. W. Bardin of the Population Council, New York, New York. The analogues tested included [(imBzl)-D-His^6,Pro^9-NEt]-GnRH; [D-Trp^6,Pro^9-NEt]-GnRH; [D-Ser-TBU)^6-NEt]-GnRH; [D-Trp^6]-GnRH; [AcD-Pro^1,pFD-Phe^2, D-$Trp^{3,6}$]-GnRH; [4CH_3-D-Phe^6,Pro^9-NEt]-GnRH; [4NO_2-D-Phe^6,Pro^9-Net]-GnRH, as well as native GnRH. The hCG was obtained commercially (A.P.L., Ayerst, Montreal, Quebec, Canada). Radiolabelled progesterone was obtained from New England Nuclear (North Billerica, Massachusetts).

The radioimmunoassay for progesterone has been validated previously for this system.[2] Assay blanks were subtracted where appropriate to correct for cross-reactivity of the substrates. Two to four replicates were performed for each incubation, and a single aliquot of each was assayed. Separate incubations were used to estimate recovery, and all data were corrected for recovery. Statistical comparisons were performed with a one-way analysis of variance.

Results

Dispersed cells from the chorion or decidua secreted progesterone, and this was increased markedly by the addition of pregnenolone to the incubations (Table I). As shown previously,[1,2] chorion was significantly more active in this regard than decidua. Amnion (data not shown) was almost devoid of such activity. The addition of hCG or GnRH had no significant effect on the progesterone production. In further experiments (data not shown), we determined that GnRH and seven analogues (see Material and methods) in concentrations of 10, 10^3, and 10^5 pg/ml had no effect on the conversion of pregnenolone to progesterone. In 24-hour incubations of tissue explants of chorion and decidua, the basal secretion of progesterone again was greatly increased by the addition of pregnenolone (Table II). However, we were unable to detect any use of choles-

terol or low-density lipoprotein cholesterol for progesterone synthesis by either tissue. In these experiments we did not detect a difference in basal progesterone secretion or conversion of pregnenolone to progesterone between the tissues obtained from the patients who had spontaneous onset of labor compared with those from patients delivered by elective cesarean section before labor.

Use of other steroids for progesterone synthesis is shown in Table III. Tissue explants of amnion show very little basal secretion of progesterone in 24-hour incubations and demonstrate no ability to use pregnenolone or pregnenolone sulfate as a substrate. However, 20α-dihydroprogesterone is readily converted to progesterone, and tissues obtained from women who have a cesarean section before labor perform this activity better than those obtained from patients after spontaneous onset of labor and vaginal delivery.

Chorion explants used pregnenolone, its sulfate, and 20α-dihydroprogesterone for progesterone synthesis. The increased ability of tissues from cesarean section to use 20α-dihydroprogesterone approached statistical significance ($p = 0.08$). Decidua also was able to convert all three substrates to progesterone but to a much lesser extent than chorion. However, when provided with pregnenolone or its sulfate as substrate, the decidual explants obtained before labor secreted more progesterone than those obtained after spontaneous labor and vaginal delivery.

The data of Table III clearly established the relative ability of the three tissues to secrete progesterone. Chorion is greater than decidua, which is greater than amnion, except in the presence of 20α-dihydroprogesterone when amnion secretes more progesterone than decidua.

The endogenous tissue concentrations of progesterone are approximately 4 ng/mg of tissue protein (Table IV). In the 10 patients in either subgroup or in the total group, the concentration of progesterone was not different between chorion and decidua, but both were greater than amnion ($p < 0.05$). There was no significant change in tissue concentrations of progesterone with increasing distance from the placenta (Table V).

Comment

We have demonstrated that all three layers of human fetal membranes have the ability to secrete progesterone. Chorion is the most active layer in this regard but appears to show no significant change associated with the timing of the onset of labor. Decidua, though less active than chorion, does show a significant decline in the ability to produce progesterone associated with the onset of labor. The increased ability of decidua to use pregnenolone for progesterone production was not

Table V. Endogenous tissue concentrations of progesterone in full-thickness pieces of human fetal membranes in relation to distance from the placenta (N = 19 patients)

	Tissue progesterone concentration (ng/mg protein)	*Concentration found near the placental edge (%)*
Near placental edge	4.4 ± 0.4	
Middle	3.7 ± 0.4	88.1 ± 7.1
Distant from placenta	4.2 ± 0.5	101.6 ± 15.6

Values are mean ± SEM.

noted in the early experiments but only became apparent when larger patient groups were studied. Amnion tissue apparently possesses very little ability to produce progesterone except when provided with 20α-dihydroprogesterone as substrate. In this instance, there again appears to be a significant decline in progesterone secretion associated with the onset of labor.

The present experiments suggest that neither cholesterol nor low-density lipoprotein cholesterol are significant substrates for progesterone production by human fetal membranes. Even if longer incubations or long-term monolayer cultures of isolated cells were able to demonstrate low-density lipoprotein cholesterol usage, it would be unlikely to be of major physiologic importance in view of the apparent ability of the tissues to readily use other substrates that are available in abundant supply. Although chorion production of progesterone was greater with pregnenolone, in view of the much greater concentrations of pregnenolone sulfate available in late pregnancy, it may be that the sulfurylated form of the substrate is the most important physiologic progesterone precursor. Other studies in our laboratory[11] have demonstrated that the fetal membranes contain an active sulfohydrolase enzyme that possesses a lower Michaelis constant for pregnenolone sulfate than for either estrone sulfate or dehydroepiandrosterone sulfate. Currently it is unclear whether all sulfurylated steroids share the same sulfohydrolase enzyme or whether there are separate substrate-specific enzyme subtypes. The regulation of sulfohydrolase activity for pregnenolone sulfate may be an important determinant of ultimate progesterone secretion by these tissues.

Our present experiments were unable to detect any effect of hCG or GnRH on progesterone secretion. In this respect, the chorion trophoblast appears to behave in a different fashion than placental trophoblast, where progesterone production is influenced by GnRH.[6, 7] There remains some confusion as to whether progesterone secretion is increased[6] or decreased[7] by exogenous GnRH in cultures of placental trophoblast.

We have noted[1, 3] previously that androgens may inhibit the conversion of pregnenolone to progesterone. Estrone and estradiol also appear to have an inhibitory effect on progesterone production in dispersed cells,[1] but this was not observed with the tissue explant system.[3] It has been demonstrated that 5α-reduced metabolites such as 5α-dihydrotestosterone and 5α-pregnanediol, when coincubated with pregnenolone, lead to an increase in progesterone secretion. This observation with 5α-dihydrotestosterone suggests that the effect is caused by inhibition of the 5α-reduction metabolic pathway rather than an oxidation of the 5α-reduced metabolite back to progesterone. The potential importance of 20α-dihydroprogesterone as a precursor to progesterone is of interest. It has been demonstrated isotopically that this is caused by a conversion of the reduced metabolite back to progesterone rather than an inhibition of further metabolism of endogenously produced progesterone.[12] It has become apparent that the enzyme 20α-hydroxysteroid dehydrogenase, which catalyzes this interconversion, is the same active site on the same molecule as the enzyme 17-hydroxysteroid dehydrogenase that catalyzes the interconversion of estrone and estradiol.[13, 14] Thus the enzyme that inactivates progesterone by reduction at the 20 position is the same enzyme that increases the biologic activity of estrone by converting it to estradiol. A change in the velocity of this enzyme may have a significant effect on the biologic estrogen-progesterone activity within local tissues. Ongoing experiments in our laboratory involve the investigation of the kinetics of the 17,20-hydroxysteroid dehydrogenase enzyme.

When comparing the ability of the fetal membrane tissues to produce progesterone with the endogenous progesterone concentrations, it appears quite feasible that the local tissues are capable of synthesizing complete local requirements. The lack of demonstration of a gradient of progesterone with increasing distance from the placental edge suggests that simple diffusion of progesterone from the placenta does not account for local tissue concentrations. These findings are compatible with our hypothesis that regulation of local progesterone production may be the principle regulator of local progesterone tissue concentrations.

Although we were unable to demonstrate a change in tissue progesterone concentrations associated with the timing of the onset of labor, this does not preclude a significant change in progesterone concentrations at some important intracellular sites. Several lines of evidence indicate that progesterone may influence prostaglandin generation, and this in turn may determine myometrial contractility.[15] Thus it is possible that the provision of substrate and the activity of enzymes, particularly steroid sulfohydrolase and 17,20-hydroxysteroid dehydrogenase may regulate local tis-

sue progesterone concentrations, which in turn may influence the timing of the onset of parturition.

Antepartum predictors of fetal distress in postterm pregnancy

Clifford J. Bochner, M.D., Arnold L. Medearis, M.D., Jane Davis, M.D., Gary K. Oakes, M.D., Calvin J. Hobel, M.D., and Maclyn E. Wade, M.D.

Los Angeles, California

The purpose of this study was to determine the efficacy of combining nonstress testing with ultrasound assessment of amniotic fluid volume for the antenatal evaluation of the postterm fetus. Postterm patients (884) were managed with amniotic fluid assessments and nonstress tests (including evaluation for variable and late decelerations) twice a week. There were no perinatal deaths or major neonatal morbidity. However, the antenatal testing sensitivity, specificity, negative, or positive predictive values were not improved by combining the two tests. Individually, amniotic fluid assessment was just as accurate a predictor of fetal well-being and was a significantly more sensitive test than the nonstress test. In addition, antenatal predictors of fetal distress and intrapartum signs of fetal distress were almost exclusively those reflective of umbilical cord compromise. These findings stress the importance of antenatal screening for signs of umbilical cord compromise as an early indication of potential fetal compromise. Although the results also suggest that amniotic fluid assessment is superior to the nonstress test, they do not conclusively support the use of amniotic fluid assessment as the sole parameter for postterm antenatal surveillance. (AM J OBSTET GYNECOL 1987;157:353-8.)

antepartum signs suggestive of uteroplacental insufficiency, including the absence of fetal heart rate (FHR) reactivity and/or the presence of late decelerations.[1, 3] However, the use of these tests in postterm pregnancies has been criticized because of their documented high percentage of false positive results and instances of falsely reassuring results.[5, 6]

In recent years clinical studies have noted that there are additional antepartum signs suggestive of fetal compromise in postterm pregnancies, including variable decelerations on FHR tracings and decreased amniotic fluid on ultrasound examination.[2, 6-8] These findings have been associated with a significantly increased incidence of poor perinatal outcome even when the traditional FHR signs of uteroplacental insufficiency were not present.

The purposes of this study were (1) to determine whether the combined use of NST and ultrasound amniotic fluid assessment improves the accuracy of postterm antepartum testing and (2) to develop insight into the importance of postterm assessment of antepartum parameters reflective of umbilical cord compromise relative to parameters reflective of uteroplacental insufficiency.

Material and methods

The study population consisted of 884 uncomplicated cases of postterm patients referred to the Cedars-Sinai Medical Center's antepartum testing unit between January 1, 1983 and May 1, 1986. Patients were referred from its clinics, private practices, and an affiliated health maintenance organization. These patients had all reached 41 to 42 completed weeks of gestation. Gestational age was determined by using combinations of early dating criteria, including an accurate last menstrual period, first trimester uterine examination, timing of initial auscultated fetal heart tones, and first- or second-trimester ultrasound examination. To be included in the study patients had to be delivered within 4 days of antepartum testing, be beyond 42 completed weeks of gestation at delivery, and had to have received a trial of labor.

Antenatal evaluation. A standard fetal monitor equipped with an ultrasound transducer and external tokodynamometer was used to record uterine contractions, FHR, and fetal movements. Amniotic fluid volume was evaluated with an ADR linear-array real-time ultrasound scanner (Model 4000, Advanced Technology Limited, Seattle, Washington) by placing a transducer perpendicular to the uterine wall and measuring the largest vertical pocket of amniotic fluid.

NST interpretations were classified by the criteria of Keegan and Paul.[9] The CSTs were performed and classified according to the standard protocol and criteria of Freeman et al.[1] The FHR strips were also reviewed for bradycardias (decrease of 40 bpm or rate <90 bpm for longer than 1 minute[10]) and significant variable decelerations (decrease of at least 15 bpm from baseline for longer than 15 seconds, excluding those after an acceleration[11]). The amniotic fluid volume was considered adequate if at least one pocket measured 3 cm vertically and was considered decreased if the largest vertical pocket was <3 cm.

At this time there is no consensus regarding the ultrasound definition of decreased amniotic fluid. Previous studies[12] have shown an increased incidence of fetal distress related to vertical pockets <1 cm[4] or 2 cm.[12] Therefore, as a conservative measure, a 3 cm vertical pocket was chosen to minimize false negative results.

The twice-weekly antepartum testing protocol included amniotic fluid assessment, NSTs, and, when necessary, CSTs. The NSTs were performed for up to 40 minutes, with abdominal stimulation if the test was not reactive after 20 minutes, followed by amniotic fluid assessment. A nonreactive NST was repeated 2 hours later if the amniotic fluid was determined to be adequate and the cervix was unfavorable for induction. A CST was done if the NST was again nonreactive. If the CST was negative, patients were retested in 3 to 4 days. Abnormal testing that led to labor induction included (1) decreased amniotic fluid, (2) bradycardias or repetitive variable or late decelerations during the NST or CST, (3) a nonreactive NST in a patient subsequently noted to have an inducible cervix. Patients with normal testing were seen twice a week until they went into labor or labor was induced at the discretion of their personal physician.

All patients were managed with continuous electronic FHR monitoring throughout labor. Fetal distress in labor was defined clinically as either (1) repetitive late decelerations, (2) repetitive moderate to severe variable decelerations with either a pH of <7.20 or decreased variability, or (3) prolonged bradycardia. Monitor tracings were classified in accordance with definitions described by Freeman and Garite.[13]

Data analysis. The sensitivity, specificity, negative, and positive predictive values for fetal distress were calculated for the NST and amniotic fluid volume assessment, individually and combined. Statistical analyses were done with χ^2, Fisher's exact test, or McNemar's test, as appropriate. A p value <0.05 was considered statistically significant.

Results

The intrapartum and neonatal outcomes for the study population are presented in Table I. The last NST and amniotic fluid assessment were normal in 715 (80.9%) patients and abnormal in 169 (19.1%). Of the 169 patients with abnormal testing results, 29 had decreased amniotic fluid, 39 had nonreactive NSTs, 32 had variable decelerations, eight had late decelerations,

and 61 had combinations of more than one abnormal parameter. There were no perinatal deaths or major neonatal morbidity, including seizures, severe meconium aspiration, or apnea. However, the group with abnormal final antepartum testing results did have a significantly higher incidence of cesarean section for fetal distress as compared with the group with normal testing ($p < 0.001$). Of the 33 patients who had cesarean sections for fetal distress, 32 had either moderate-to-severe variables or prolonged bradycardias, and one had combined repetitive variable and late decelerations. The NST (including evaluation for decelerations) is compared with amniotic fluid assessment in Table II. For both tests there was a highly significant difference in the incidence of fetal distress when the last test was abnormal as compared with normal ($p < 0.01$). Both tests had extremely accurate negative predictive values (>98%) and poor positive predictive values (<30%). Although amniotic fluid assessment had a significantly greater sensitivity than the NST ($p < 0.01$), the specificities and negative predictive values were not significantly different between the tests. It was not appropriate to statistically compare the positive predictive values because patients were not randomized to alternate management schemes.

The predictive values of amniotic fluid assessment in conjunction with a reactive or abnormal NST and the NST in conjunction with adequate or decreased amniotic fluid are shown in Tables III and IV.

The negative predictive value of a reactive NST combined with adequate amniotic fluid was not significantly greater than that of either test alone (Tables II to IV). The positive predictive values of decreased amniotic fluid, a nonreactive NST, variable decelerations, and late decelerations were 20.7%, 2.5%, 6.3%, and 0%, respectively, when each of the other parameters were normal (Table IV).

When amniotic fluid was adequate, its negative predictive value was not significantly different whether the NST was reactive or nonreactive (Table IV). However, its negative predictive value was significantly less when the NST contained variable decelerations. When amniotic fluid was decreased, its positive predictive value was not significantly different, whether the NST was reactive, nonreactive, or contained decelerations (Table IV). The negative predictive value of a reactive NST was significantly less when amniotic fluid was decreased, whereas the positive predictive value of an abnormal NST was significantly less when amniotic fluid was adequate (Table IV).

The testing sensitivities of the abnormal antepartum

testing parameters are listed in Table V. The abnormal NST parameters combined with decreased amniotic fluid helped to detect 27 (82%) of the patients with eventual fetal distress. This was a significantly greater percentage than was identified by the NST alone ($p < 0.01$) but was not a significantly greater percentage than was identified by amniotic fluid assessment alone. The combination of decreased amniotic fluid and/or variable decelerations helped to detect 26 of these 27 patients.

Comment

The overall incidence of fetal distress and neonatal morbidity in this study was minimal, even though there was a significantly increased incidence of fetal distress in the abnormal testing group. This suggests that intervention in the abnormal testing group was undertaken before significant fetal compromise. Although it is tempting to credit antepartum testing for these excellent results, the low incidence of perinatal compromise may instead be the result of the fact that this was a closely followed population, in which patients considered to be at high risk were delivered before 42 completed weeks of gestation.

However, the study does stress the importance of postterm antenatal screening for signs of umbilical cord compromise as an early indicator of potential fetal compromise, relative to signs of uteroplacental insufficiency. This is demonstrated by the fact that of all the patients with eventual intrapartum fetal distress who were correctly identified by antenatal testing, decreased amniotic fluid and/or variable decelerations detected all but one (Table V). In addition, decreased amniotic fluid and variable decelerations were associated with a significantly increased incidence of fetal distress, even when the NST was reactive (Table III). Conversely, nonreactive NSTs or late decelerations were the only abnormal parameters in just 28% of the abnormal tests, and they were not associated with an increased incidence of fetal distress as long as amniotic fluid was adequate.

The intrapartum FHR tracing signs of fetal distress were reflective of these findings. Of the 33 cesarean sections for fetal distress, 97% were done because of either prolonged bradycardias or moderate to severe variable decelerations. These findings further support and extend to the antepartum period the findings of Leveno et al.,[14] associating the pathophysiology of postterm fetal distress almost exclusively with signs reflective of umbilical cord compression. As discussed by Leveno et al.,[14] this does not exclude uteroplacental insufficiency as the primary cause of postterm fetal compromise. It may be that antepartum signs of umbilical cord compromise are just an earlier reflection of uteroplacental insufficiency than the absence of FHR reactivity or the appearance of late decelerations.

This study also suggests that antepartum testing accuracy is not improved by combining the NST with amniotic fluid assessment. Although the NST and amniotic fluid assessment were each highly accurate predictors of fetal well-being, their accuracy was not improved when the tests were combined (Tables II and III). In addition, neither adequate amniotic fluid nor a reactive NST provided adequate assurance of fetal well-being to avoid pregnancy intervention when the other test was abnormal. The only exception was that adequate amniotic fluid, in the presence of a nonreactive NST without variables, was as reassuring of fetal well-being as when the NST was reactive. Individually and combined, these tests were poor predictors of intrapartum fetal distress. However, the low incidence of fetal distress in this population makes it extremely difficult to design a test with a high positive predictive value without having a detrimental effect on the testing specificity and negative predictive values. Lastly, the sensitivity of the combined tests was not statistically improved over the use of amniotic fluid assessment alone.

Because morbidity was minimal and the results did not show any statistical improvement to testing accuracy from combining the two tests, we considered whether one of these tests could be used alone as the sole means of postterm surveillance. Individually, amniotic fluid assessment was an extremely accurate predictor of fetal well-being (98.6%), and it was a significantly more sensitive test than the NST. These findings, as well as the excellent results obtained by Crawley et al.,[8] who used only amniotic fluid assessment, and the fact that amniotic fluid assessment is a fast and inexpensive procedure suggest that it is a superior test to the NST for postterm fetal surveillance. However, the results of this study do not conclusively support the use of amniotic fluid assessment alone for postterm fetal surveillance. We cannot discount that a prospective randomized study may show that amniotic fluid assessment combined with either an NST, or FHR screening for variable decelerations has a greater testing accuracy than amniotic fluid alone. Perhaps the results of this study and the one by Crawley et al.[8] will permit such a prospective study.

Ultrasound diagnosis of abruptio placentae with fetomaternal hemorrhage

Michael S. Cardwell, M.D.
Rockford, Illinois

Fetomaternal hemorrhage and abruptio placentae may occur concurrently. A prospective study was done to determine the incidence of fetomaternal hemorrhage in noncatastrophic cases of abruptio placentae consistent with sonographic findings. Significant fetomaternal hemorrhage was found in 75% of noncatastrophic cases. Implications of conservative management of abruptio placentae with fetomaternal hemorrhage are discussed. (Am J Obstet Gynecol 1987;157:358-9.)

Key words: Abruptio placentae, fetomaternal hemorrhage

Fetomaternal hemorrhage and abruptio placentae are two relatively common complications of pregnancy. Fetomaternal hemorrhage occurs in approximately 50% of all pregnancies and abruptio placentae has an incidence of 1/120 deliveries.[1] Fetomaternal hemorrhage can occur as a result of abruptio placentae as there is a breach in the integrity of the placental circulation.

In some instances abruptio placentae may occur without significant clinical signs and may be managed conservatively. These cases usually occur in early pregnancy and the diagnosis is confirmed by ultrasound examinations. To determine the relationship between ultrasound findings of abruptio placentae and fetomaternal hemorrhage in noncatastrophic cases a prospective study was done.

Material and methods

The study period was from July 1, 1985, through June 30, 1986. All patients with ultrasound examinations performed in the Department of Maternal-Fetal Medicine in which marked sonographic appearance of abruptio placentae was present in association with clinical signs and symptoms were chosen for the study. During this period 1225 consecutive ultrasound examinations with the use of a Toshiba SAL-50 real-time linear scanner with either a 4.0 or 5.0 MHz transducer were performed exclusively by M. S. C. for a variety of indications.

The ultrasound diagnosis of abruptio placentae was made if a retroplacental lucency suggestive of pooled blood or clot was apparent or if separation of the chorion-amnion from the uterine wall was present. Fetomaternal hemorrhage was evaluated with the Kleihauer-Betke stain. The results of the stain were reported as a ratio of fetal cells to adult cells. The quantity of the fetomaternal hemorrhage was determined by the formula derived by Mollison[2]:

$$\text{Fetomaternal hemorrhage (ml fetal red blood cells)} = 2400 \times \frac{\text{fetal cells}}{\text{adult cells}}$$

Results

Eight patients had both sonographic and clinical findings suggestive of abruptio placentae. The study group comprised these patients. Four patients presented with catastrophic indications for immediate delivery by cesarean section, for example, fetal distress, severe vaginal bleeding, or severe pain. No Kleihauer-Betke staining was performed in these patients because of the urgency for immediate delivery. The other four patients presented with clinical and sonographic evidence of abruptio placentae but the condition was not life-threatening to the mother or the fetus. Kleihauer-Betke stains were used to determine the presence of fetomaternal hemorrhage in the noncatastrophic group.

The two groups differ in several aspects. The catastrophic group had gestational ages ranging from 29 to 34 weeks, with a mean of 31.8 weeks. The noncatastrophic group's gestational age varied between 14 and 31 weeks with a mean of 21.8 weeks. The percentage of placental surface estimated by the attending obstetrician to have been separated in the catastrophic group varied from 20% to 50% of the total area. The mean separation was 35%. Only one patient in the noncatastrophic group had evidence of abruptio placentae at the time of delivery. The mean gestational age at delivery was 37.5 weeks for the noncatastrophic group and 31.8 weeks for the catastrophic group. Neither group experienced a neonatal death.

Three of four patients in the noncatastrophic group had evidence of fetomaternal hemorrhage. The transplacental hemorrhage ranged from no fetal blood cells to 72 ml of fetal blood cells detected with a mean of 31.5 ml of fetal red blood cells. One patient required 6 ampules of RhoGam to protect her from Rh isoimmunization.

Comment

In this prospective study abruptio placentae was diagnosed in eight of 1225 ultrasound examinations done for a variety of indications. This gives an incidence of 0.65%, which agrees with the cited occurrence of abruptio placentae of 0.49% to 1.29%.[1] Fetomaternal hemorrhage was verified in 75% of the noncatastrophic cases and was demonstrated to be significant with an average fetal red blood cell loss of 31.5 ml. Fetomaternal hemorrhage is known to occur in approximately 50% of all pregnancies but in less than 1% of the patients is the bleeding >5 ml.

The outcomes of the mothers and infants in this series were generally good; however, serious complications can occur with fetomaternal hemorrhage. Fetomaternal hemorrhage has been associated with antepartum intrauterine fetal death, neonatal anemia, anaphylatic shock of the mother, and sensitization to the Rh system and other blood groups. Hydrops fetalis and intrauterine fetal atrial fibrillation has also been reported in association with fetomaternal hemorrhage. If conservative management is elected in patients with noncatastrophic abruptio placentae, documentation and quantification of fetomaternal hemorrhage are imperative.

Acute atherosis in preeclampsia: Maternal determinants and fetal outcome in the presence of the lesion

T. Y. Khong, M.B., M.Sc., J. M. Pearce, and W. B. Robertson, M.D.
London, England

In 39 patients with preeclampsia a detailed analysis of some maternal factors, fetal outcome, and a histologic assessment of the presence or absence of acute atherosis in maternal intrauterine vessels has been done. There was no statistically significant relation between acute atherosis and parity, degree of proteinuria, severity and duration of hypertension, or antihypertensive therapy. These findings do not support a purely hemodynamic pathogenesis for the vasculopathy. Fetal outcome was only marginally worse in the preeclamptic patients who developed acute atherosis. (Am J Obstet Gynecol 1987;157: 360-3.)

Key words: Acute atherosis, preeclampsia, maternal factors, fetal outcome

A defective maternal vascular response to placentation has been demonstrated in pregnancies complicated by preeclampsia and by small for gestational age infants.[1-3] In addition, a vasculopathy called acute atherosis[4] is seen in intrauterine vessels in preeclampsia.[5] The arteries undergo fibrinoid necrosis accompanied by lipophage infiltration of the damaged vessel wall and a perivascular mononuclear cellular infiltrate.[6-9]

The significance of this lesion has been highlighted by a recent study that showed a lower birth weight in pregnancies when acute atherosis is found in vessels in the placental bed.[10] It also has been suggested[8] that these lesions offer the best explanation for the decidual necrosis and subsequent abruptio placentae and antepartum hemorrhage and for maternal vascular thrombosis leading to placental infarction.

The pathogenesis of acute atherosis is still unclear. Inappropriate immunologic fetal-maternal interactions have been postulated.[5, 8, 11-13] Other studies have suggested that preeclampsia associated with acute atherosis is more severe than that without atherosis[6] and that acute atherosis is seen with increasing frequency as the severity of the preeclampsia increases.[7] To evaluate the role of hemodynamic factors in the pathogenesis of acute atherosis and the relation of the lesion to maternal and fetal factors, we undertook a retrospective study of the maternal and fetal parameters in preeclamptic pregnancies.

for histologic assessment were studied. Preeclampsia was defined as proteinuric hypertension of >140/90 mm Hg on two occasions at least 6 hours apart. Parity, gestational age at delivery, maximum blood pressure, degree of rise in blood pressure, degree of proteinuria, interval between the onset of proteinuric hypertension and delivery, and the use of antihypertensive therapy were studied. Gestational age was calculated in early pregnancy by ultrasound measurement of the biparietal diameter or by dates of the last menstrual period. Mean arterial pressure was calculated according to Page and Christianson.[14] Proteinuria was detected by the use of a multireagent dipstick in all cases, and the maximal dipstick reading was used. In addition, the birth weight percentile, evidence of fetal distress on cardiotocography or fetal blood sampling, intrauterine growth retardation, and fetal death were recorded. The birth weight chart of Milner and Richards[15] was used for births between 28 and 32 weeks of gestation and that of Altman and Coles[16] for gestations after 33 weeks. Three twin pregnancies and three deliveries before 28 weeks of gestation were not studied for the birth weight percentile. Intrauterine growth retardation was separated into true intrauterine growth retardation on the basis of sequential ultrasonographic studies and small for gestational age infants when the birth weight was below the tenth percentile, but sequential ultrasonographic studies were not available to confirm actual growth retardation.

Because placental bed biopsies were not always available,[17] it was decided that the delivered placentas were to be used as the study material. From each placenta

numerous blocks (nine to 12) of the basal plate and between two and four amniochorion rolls, prepared according to the method of Zeek and Assali,[6] were examined histologically. From this assessment the pregnancies were classified into those with and those without acute atherosis.

The maternal data of the two groups were analyzed for differences. When appropriate, the differences between mean values were compared with the two-tailed t test for unpaired data, and differences between proportions were compared with the χ^2 test. Tests were considered significant at the 5% level.

Results

Acute atherosis (Fig. 1) was detected in maternal vessels in 18 of the 39 patients (46%). Except for gestational age at delivery, when there was a statistical difference, analysis of the maternal parameters showed no significant differences between the two groups of patients (Table I). No statistical differences in the fetal outcome between the two groups could be demonstrated (Table II). There were three stillbirths in the acute atherotic group and four neonatal deaths in the nonacute atherotic group.

Comment

Because acute atherosis is focal, it may be expected that false negative findings of absence of acute atherosis would be encountered because of selection factors and the unavailability of placental bed biopsies from all cases. However, we believe that the large number of blocks taken from each placenta was sufficient to enable the majority of acute atherotic lesions to be detected if they were present. Our incidence of acute atherosis in preeclampsia (46%) is in accordance with the findings of other workers who used placental and placental bed material that ranged from 41.8% to 47.8%.[6, 12] Maqueo et al.[7] found the incidence to be 22%, 42%, and 65% in mild and severe preeclampsia and in eclampsia, respectively.

The mean gestational age at the time of delivery was almost 4 weeks earlier in the acute atherotic group; this may be a reflection of the somewhat poorer fetal outcome in this group. The incidence of fetal distress, small for gestational age infants, low birth weight percentiles, and stillbirth rate was higher in the acute atherotic group but that of intrauterine growth retardation was lower; however, these differences did not attain statistical significance. This finding contrasts with a recent study[10] that shows a lower mean birth weight in preeclamptic pregnancies with acute atherosis, but those results may be due to the failure of the authors to examine the maternal vessels attached to the amniochorion. Maqueo et al.[7] found an increased incidence of acute atherosis and a decreasing birth weight with severity of the disease, but the gestational ages in their cases decreased concomitantly. The stillbirth rates of their patients with mild and severe preeclampsia were not statistically different.

Although the number of cases studied may be small, analysis of the maternal factors did not support the concept that hypertension in itself causes acute atherosis or that the incidence of acute atherosis increased with the severity or duration of the condition.[6, 7] It may be that an inappropriate immune reaction is the major determinant of acute atherosis,[5, 8, 11-13] but proof for this proposal will require further detailed studies, including human leukocyte antigen typing of the mother, the father, and the fetus.

We wish to thank Dr. J. M. Bland of the Department of Clinical Epidemiology for his advice on the statistics.

Increased fetoplacental active renin production in pregnancy-induced hypertension

Harbinder S. Brar, M.D., Siri L. Kjos, M.D., William Dougherty, M.D., Yung-Shun Do, Ph.D., Helen B. Tam, and Willa A. Hsueh, M.D.*
Los Angeles, California

Since pregnancy-induced hypertension is associated with impaired uteroplacental blood flow, we studied fetoplacental and maternal renin production in controls and subjects with pregnancy-induced hypertension. We measured total, active, and inactive (pro-) renin in maternal serum, fetal arterial and venous blood, and chorion homogenate in eight normotensive term patients and 18 patients with pregnancy-induced hypertension. No differences in active or prorenin were found in maternal blood from normal women or patients with pregnancy-induced hypertension. In contrast, fetal artery and vein, as well as chorionic tissue, contained significantly higher active renin in pregnancy-induced hypertension compared with normal subjects. No difference in fetal or chorionic prorenin was seen in the two groups. Thus active to total renin ratio was higher in the fetus and chorion of subjects with pregnancy-induced hypertension, which suggests enhanced active renin production. These results suggest that pregnancy-induced hypertension is associated with increased activity of the renin-angiotensin system in the fetoplacental unit, which is not reflected in the maternal circulation. This may be an attempt by the fetus and chorionic membranes to maintain vascular homeostasis in the face of altered uteroplacental blood flow. (AM J OBSTET GYNECOL 1987;157:363-7.)

Key words: Renin, pregnancy-induced hypertension

Decreased uteroplacental blood flow caused by vasospasm and vaso-occlusion may contribute to the pathogenesis of pregnancy-induced hypertension.[1] In general, this results in a growth-retarded fetus and smaller placenta in women with pregnancy-induced hypertension compared with normal pregnant women.[2] The vasospasm may be produced by increased circulating levels of a vasoconstrictor substance, which has been detected in the plasma of patients with pregnancy-induced hypertension.[3] However, the nature of this substance is unknown. Plasma renin activity is similar to or slightly lower in patients with pregnancy-induced hypertension compared with normal pregnant women, whereas angiotensin II levels have been reported to be slightly higher in pregnancy-induced hypertension.[4, 5] In pregnant women the chorionic membrane and uterus, as well as the fetus, can produce and secrete renin. Because of the impaired uteroplacental blood flow in pregnancy-induced hypertension, we sought to determine whether alterations in fetoplacental renin production occur in this disorder.

Material and methods

In eight normotensive and 18 term laboring patients with pregnancy-induced hypertension, we obtained maternal venous blood, fetal arterial and venous cord

Table I. Clinical parameters and renin levels in control and pregnancy-induced hypertension subjects

	Control (n = 8)	*Pregnancy-induced hypertension (n = 18)*
Maternal age (yr)	25 ± 2	25 ± 2
MAP (mm Hg)	76 ± 3	113 ± 3
Gestational age (wk)	39 ± 1	39 ± 1
Length of labor (hr)	11 ± 2	16 ± 2
Birth weight (gm)	3338 ± 122	3186 ± 160
Maternal blood		
Active renin (ng AI/ml/hr)	5.4 ± 1.5	6.6 ± 1.2
Prorenin (ng AI/ml/hr)	96 ± 20	144 ± 23
Active:total renin ratio	0.06 ± 0.01	0.05 ± 0.01

MAP = Mean arterial pressure; AI = angiotensin I.

blood, and chorion. Pregnancy-induced hypertension was defined as a hypertensive disorder of pregnancy occurring after 20 weeks of gestation with a blood pressure of 140/90 mm Hg or greater on two occasions 6 hours apart or an increase of 30 mm Hg systolic or 15 mm Hg diastolic over first-trimester blood pressure. The hypertension was associated with significant proteinuria (1+ or greater) and edema. Labor was induced in none of the normotensive and six of the hypertensive subjects. All of the hypertensive subjects received $MgSO_4$, a 4 gm loading dose followed by an infusion rate of 2 gm/hr. Three of the hypertensive subjects received either methyldopa (Aldomet) or hydralazine hydrochloride (Apresoline) during the third trimester. Two normal control subjects were delivered vaginally, while six required cesarean section. Twelve subjects with pregnancy-induced hypertension delivered vaginally, and six had cesarean section. Informed consent was signed by all patients before the study. The blood samples for renin measurements and other studies were chilled and centrifuged within 4 hours after collection, and the plasma was quickly frozen to prevent inadvertent activation of plasma renin.[6] They were stored at −20° C in a nonfrost-free freezer. Clinical laboratory data included blood urea nitrogen, serum creatinine, sodium, potassium, and uric acid, which were determined by autoanalyzer.

Active renin concentration was measured by radioimmunoassay of angiotensin I after incubation of samples with sheep angiotensinogen at 37° C, pH 7.5, in the presence of angiotensinase inhibitors.[7] Total renin was measured by acid treatment of plasma,[7] which involved dialysis against pH 3.3, 0.05 mol/L glycine buffer at 4° C for 18 hours, and then dialysis against pH 7.5, 0.05 mol/L phosphate buffer under the same conditions. Inactive (pro-) renin concentration was calculated as the difference between total and active renin concentrations. The interassay coefficients of variation of active and prorenin measurements are 6% and 15%, respectively. Measurements were compared in the two groups by means of *t* test analysis, and significance was considered at the $p < 0.05$ level.

Table II. Maternal electrolytes and renal function

	Control (n = 8)	*PIH (n = 18)*	*p value*
Na (mEq/L)	138 ± 1	139 ± 1	NS
K (mEq/L)	4.1 ± 0.1	4.0 ± 0.1	NS
BUN (mg/dl)	7.6 ± 1.8	11.6 ± 2.1	<0.05
Creatinine (mg/dl)	0.6 ± 0.1	0.9 ± 0.1	<0.05
Uric acid (mg/dl)	4.1 ± 0.3	6.8 ± 0.6	<0.05

PIH = Pregnancy-induced hypertension; BUN = blood urea nitrogen.

Chorionic membrane was homogenized at 4° C in 0.25 mol/L phosphate buffer (1:2, v/v), containing 10 mmol/L ethylenediaminetetracetate, 2 mmol/L phenylmethylsulfonyl fluoride, 2 mmol/L 8-hydroxyquinoline, 2 mmol/L benzamidine, and 20,000 kallikrein inhibitor units/L aprotinin.[7] After centrifugation of the homogenate at 10,000 rpm for 30 minutes, the supernate was removed and frozen at −20° C until assay.

Results

Clinical parameters in both groups of patients are given in Table I. There were no differences in normotensive subjects and those with pregnancy-induced hypertension with regard to maternal age, gestational age, length of labor, or infant birth weight. The mean arterial pressure was significantly higher in subjects with pregnancy-induced hypertension compared with normal pregnant women. Maternal electrolytes and renal function in both groups are shown in Table II. There were no significant differences between the mean sodium and potassium levels between the two groups, whereas subjects with pregnancy-induced hypertension had significantly higher blood urea nitrogen, creatinine, and uric acid levels compared with control subjects ($p < 0.05$; Table II).

Maternal venous blood. There was no significant difference between active renin, inactive renin, and ratio of active to total renin in subjects with pregnancy-induced hypertension compared with control subjects (Table I).

Fetal arterial blood. Plasma active and inactive renin concentration in control subjects were 10.4 ± 2.4 and 65.7 ± 9.5 ng angiotensin I/ml/hr, respectively, whereas these levels were 35.7 ± 7.8 and 71.4 ± 14.0 ng angiotensin I/ml/hr, respectively, in patients with pregnancy-induced hypertension. Inactive renin

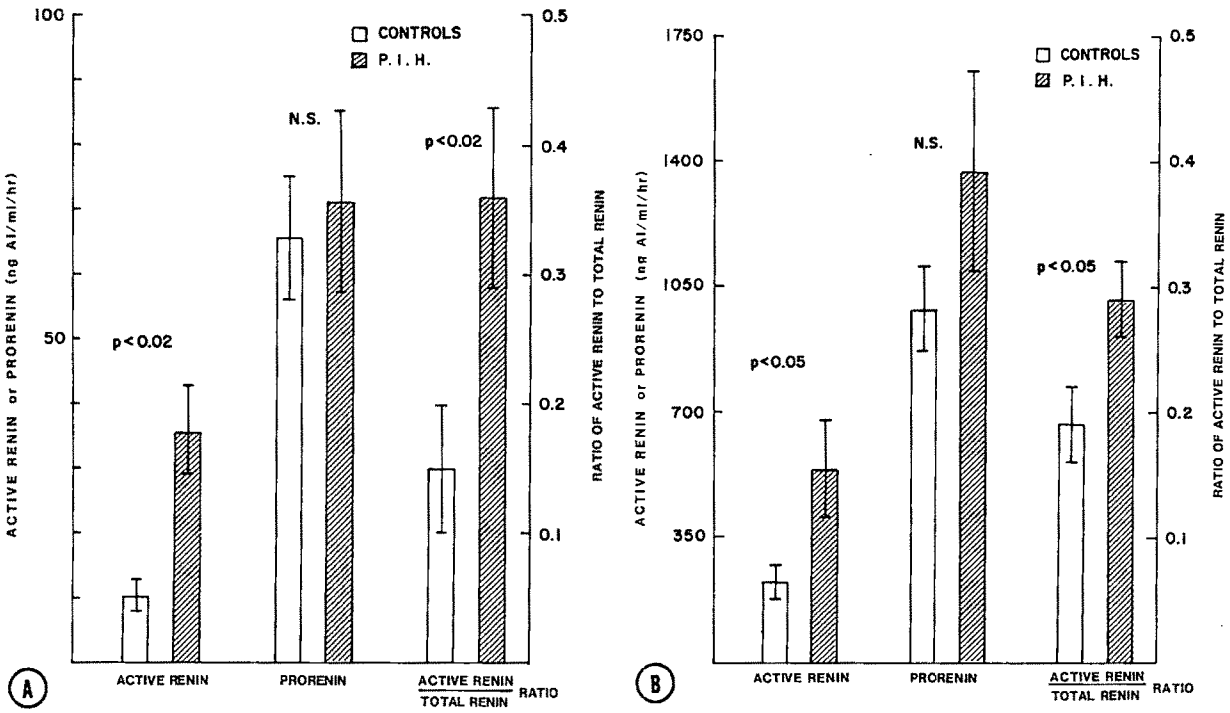

Fig. 1. Active renin and prorenin levels and active to total renin ratio in fetal arterial blood and chorion homogenate from control subjects and patients with pregnancy-induced hypertension. There were no differences between prorenin levels in fetal arterial blood (**A**) or chorion homogenate (**B**) of control subjects compared with subjects with pregnancy-induced hypertension whereas the active renin levels and the percentage of active renin were significantly higher in subjects with pregnancy-induced hypertension.

levels were not statistically different in the two groups, but samples from subjects with pregnancy-induced hypertension had significantly higher ($p < 0.025$; Fig. 1, *A*) active and total renin than did control subjects. Active to total renin ratio in subjects with pregnancy-induced hypertension (0.30 ± 0.07) was more than twice that seen in controls (0.15 ± 0.05, $p < 0.025$).

Fetal venous blood. Active and inactive renin concentrations in control subjects were 10.2 ± 3.3 and 102.21 ± 13.2 ng angiotensin I/ml/hr, respectively, whereas these levels were 44.9 ± 11.1 and 87.6 ± 18.4 ng angiotensin I/ml/hr, respectively, in blood from subjects with pregnancy-induced hypertension. Similar to fetal arterial blood, inactive renin levels were no different in the fetal venous blood of the two groups, but subjects with pregnancy-induced hypertension had significantly ($p < 0.025$) higher active and total renin than did control subjects. Active to total renin ratio in subjects with pregnancy-induced hypertension (0.30 ± 0.06) was about twice that seen in control subjects (0.15 ± 0.06, $p < 0.025$). The levels of active and inactive renin in cord arterial and venous blood were similar within the same patient.

Chorion. Homogenate of the chorionic membrane obtained from subjects with pregnancy-induced hypertension contained significantly more active renin than that of normal control subjects (542 ± 136 versus 222.5 ± 45.3 ng angiotensin I/ml/hr, respectively, $p < 0.05$). The content of inactive renin, however, was not different between the two groups (1369 ± 276 versus 988 ± 122 ng angiotensin I/ml/hr respectively, NS). Thus the active to total renin ratio was significantly higher in the chorionic membrane of subjects with pregnancy-induced hypertension compared with control subjects (0.29 ± 0.03 versus 0.19 ± 0.03, $p < 0.05$, Fig. 1, *B*).

Active renin levels in cord blood or chorionic homogenate did not correlate with maternal mean diastolic pressure, amount of proteinuria, serum creatinine, blood urea nitrogen, uric acid, sodium, and potassium, or hematocrit.

Comment

The present study is consistent with previous reports that maternal active renin concentration is normal or only slightly elevated in pregnancy, whereas inactive renin is elevated two to five times the nonpregnant range.[8] Similar levels of both active and inactive renin were seen in the blood of normal pregnant women, and several investigators have previously shown that plasma renin concentration and activity are either unchanged

or slightly decreased in subjects with pregnancy-induced hypertension compared with normal pregnant women.[5] Whether these renin levels are inappropriately high for the degree of hypertension in subjects with pregnancy-induced hypertension is still controversial.

Recent studies have demonstrated that human inactive renin is prorenin, the biosynthetic precursor of active renin.[9] Late in pregnancy the uterine fetoplacental unit contributes to the elevated prorenin levels in the maternal circulation.[10] Chorionic membranes contain large quantities of inactive renin,[11, 12] and human chorionic cells in culture secrete prorenin in relatively larger quantities compared with active renin. Factors regulating chorionic cell renin production are unknown. In the fetus the juxtaglomerular apparatus is well developed by 3 months' gestation. The fetal kidney is the major source of fetal renin, since cord blood levels of plasma renin activity are low in the anephric fetus.[13] Since absolute quantities of prorenin are increased in cord blood, prorenin may be the major form of renin secreted by the fetal kidney. Alternatively, the metabolic clearance of prorenin may be decreased in the fetus.

Because of the large quantities of prorenin secreted by the chorion and the fetal kidney, the finding of increased active renin in cord blood and chorion in pregnancy-induced hypertension was unexpected. Since prorenin levels from these sources are not significantly different in normal pregnancy and pregnancy-induced hypertension, the increased active renin levels in pregnancy-induced hypertension result from enhanced production of fetal and chorionic active renin and hence total renin production rather than from inadvertent activation of prorenin in chorionic homogenate or cord blood. An increased potential for inadvertent activation of prorenin exists in pregnancy-induced hypertension because of the increased activation of clotting factors in pregnancy-induced hypertension that are capable of activating renin.[6] However, the lack of significant increases in active renin in the maternal circulation in pregnancy-induced hypertension also argues against this possibility.

Whether the rise in chorionic and cord blood active renin preceded or resulted from maternal hypertension is an intriguing question. Fetal stress, such as hemorrhage, increases plasma renin activity in lambs and ewes.[14] In the rabbit, uteroplacental ischemia induces uterine renin release, which may contribute to the regulation of maternal systemic blood pressure.[15] Studies by Ferris and Weir[16] further indicate that one function of the uteroplacental renin angiotensin system is to maintain uteroplacental blood flow. Administration of converting enzyme inhibitor to pregnant rabbits acutely decreased uteroplacental blood flow and chronically resulted in smaller fetuses and increased fetal deaths. Thus fetal stress and hypoxia caused by a decrease in uteroplacental perfusion, which is known to occur in pregnancy-induced hypertension, may activate the fetal and chorionic renin-angiotensin systems. These results are consistent with the previous data of Broughton et al.,[17] who found increased levels of angiotensin I in the cord blood of infants born to mothers with hypertension compared with normal mothers. However, a recent report by Symonds et al.[18] showed no significant difference in plasma renin activity or active renin concentration in the cord blood of infants from normotensive women compared with that of hypertensive women. The reason for the differences in results between the two studies may be related to differences in the handling of patients. In the study of Symonds et al., labor was induced in seven of 10 hypertensive patients. Whether the patients received $MgSO_4$ or other treatment is not indicated. In our study of 18 subjects with pregnancy-induced hypertension, six had induction of labor and all received $MgSO_4$. Whether induction of labor or $MgSO_4$ affects active renin production by the chorion or fetus remains to be determined. Increases in serum magnesium concentration directly enhance renal production of renin.[19] The significance of this effect on the fetal kidney seems unlikely in the present study, since maternal active renin levels were not elevated. However, renin levels in patients with pregnancy-induced hypertension may have been lower had they not received magnesium. Although both groups of patients received similar infusions of Ringer's lactated solution, it is possible that the data might not reflect the condition before labor and some of the values may have been affected by intravascular volume.

In our pregnant women with pregnancy-induced hypertension, the impact of fetal stress could not be assessed directly, since fetal outcome and birth weight were not different from that of normal pregnancies. Serum creatinine and uric acid were significantly higher in pregnancy-induced hypertension compared with normal pregnancies, which was expected.[2] However, active renin levels in cord blood or in chorion in pregnancy-induced hypertension did not correlate with maternal blood pressure, proteinuria, serum creatinine, uric acid or electrolytes, gestational age, maternal age, or length of labor. Further studies in a larger population of patients with pregnancy-induced hypertension and in patients with evidence of intrauterine growth retardation may be necessary to determine more precisely the relationship between fetal stress and renin production. Nevertheless, this is the first study to demonstrate differences in placental and fetal renin systems compared with the maternal system in pregnancy-induced hypertension. The results suggest that perhaps imbalances in fetoplacental vasoconstric-

tor and vasodilator systems may be associated with hypertension resulting from pregnancy.

Digoxin-like immunoreactive substance in fetuses with and without cardiac pathology

C. P. Weiner, M.D., S. Landas, M.D., and T. J. Persoon, M.S.
Iowa City, Iowa

The concentration of digoxin-like immunoreactive substance was measured by immunoassay in umbilical venous blood from six normal and 19 fetuses with a variety of cardiac and noncardiac disorders. Fetal blood was obtained either by percutaneous umbilical blood sampling (n = 13) or at delivery (n = 12). Three women received digoxin for fetal indications. Healthy control fetuses had significantly less digoxin-like immunoreactive substance measured (mean concentration below the limit of the assay sensitivity) than was found in ill fetuses whose mothers received digoxin ($p < 0.005$). However, the fetal concentrations of immunoreactive digoxin in fetuses with a cardiac abnormality were similar whether the mother had (0.93 ± 0.4 ng/ml) or had not (1.27 ± 0.4 ng/ml) received digoxin ($p = 0.1452$). Although there was a significant negative correlation between digoxin concentration and gestational age ($R = -0.5079$, $p < 0.01$), the youngest fetuses examined were generally the sickest. The correlation with gestational age was not significant if the normal control fetuses were excluded. One fetus with a cardiac tachyarrythmia was examined during and after transplacental therapy. There was no change. It is possible that previously measured "digoxin" in "treated" fetuses represents digoxin-like immunoreactive substance and that only small amounts of maternally administered digoxin actually reach the ill fetus. Our findings suggest that a randomized trial of maternal digitalization for the treatment of fetal supraventricular tachycardia is essential prior to its acceptance as effective therapy. (Am J Obstet Gynecol 1987;157: 368-71.)

Key words: Digoxin, digoxin-like immunoreactive substance, fetal arrythmia

Since the first successful case reported in 1980,[1] transplacental pharmacologic treatment of fetal supraventricular tachycardia has become firmly entrenched in the literature and reference textbooks despite the lack of controlled trials.[2, 3] Almost without exception, digoxin has been the drug of first choice. The reported interval from initiation of drug therapy to fetal response ranges from immediately to 35 days.[4] This status as drug of choice is presumably based on multiple studies demonstrating a near 1:1 maternal-fetal distribution of maternally administered digoxin.[5-7] In light of the rather recent discovery of a digoxin-like immunoreactive substance in patients with a variety of disorders,[8-12] the absence of data from non–digoxin-exposed control fetuses may be of significance. Frustrated by repetitive failures with transplacental digoxin therapy, despite administering drug sufficient to produce maternal toxicity, we initiated an investigation 3 years ago of fetal digoxin-like immunoreactive substance concentration in both normal and abnormal fetuses whose mothers had and had not received exogenous digoxin. The results demonstrate a need for a randomized trial of maternal digitalization prior to concluding it is effective, much less the first-line treatment for fetal supraventricular tachycardia.

Subjects and methods

Twenty-five fetuses were studied: six healthy fetuses of healthy parturient women, four fetuses whose mothers had preeclampsia but who were otherwise healthy, four fetuses with either supraventricular tachycardia or cardiac failure due to structural abnormalities whose mothers received digoxin, and 11 fetuses (12 samples) with a variety of cardiac and noncardiac disorders whose mothers had not received digoxin. Fetal blood was obtained from the umbilical vein either at delivery (n = 13) or by percutaneous umbilical cord blood sampling (n = 12). Digoxin was measured by an immunoassay (Digoxin I, Abbott TDX) used according to manufacturer's instructions. The methodology remained unchanged during the study period. This assay, like other immunoassays, does not distinguish between digoxin-like immunoreactive substance and exogenously administered digoxin.[12] For our analyses we used subprograms from ABSTAT, release 4, and included analysis of variance, correlation coefficients, and *t* tests.

Table I. Digoxin levels in normal and abnormal fetuses with and without maternal digoxin therapy

Group	*Abnormality*	*Gestational age (wk)*	*Umbilical vein "digoxin" (ng/ml)*	*Maternal vein "digoxin" (ng/ml)*	*Perinatal outcome*
Control					
1	—	38	<0.2	<0.2	Alive and well
2	—	37	<0.2	<0.2	Alive and well
3	—	40	<0.2	<0.2	Alive and well
4	—	39	<0.2	<0.2	Alive and well
5	—	38	<0.2	ND	Alive and well
6	—	39	0.4	ND	Alive and well

7	—	36	0.5	ND	Alive and well
8	—	38	0.5	ND	Alive and well
9	—	37	0.3	ND	Alive and well
10	—	35	0.7	ND	Alive and well
Maternal digoxin therapy					
11	SVT with atrial flutter; digoxin plus propranolol	37	0.5	1.2	Responded to digoxin and cardioversion after delivery
12	SVT	32	1.0	1.7	Responded to digoxin and cardioversion after delivery
13	Nonimmune hydrops associated with Ebstein's malformation	34	1.4	1.9	Neonatal death
14	SVT	24	0.8	1.8 to 2.6	Successful direct fetal therapy
No maternal digoxin					
15	Nonimmune hydrops secondary to SVT	35	1.6	ND	Tricuspid insufficiency—converted with transesophageal pacemaker

ND = Not done; SVT = supraventricular tachycardia.

continued

Results

Only one control fetus had a detectable concentration of digoxin-like immunoreactive substance is excess of the lower limit for the assay (0.2 ng/ml) (Table I). Each fetus whose mother received digoxin had measured concentrations significantly higher than those of the healthy control fetuses ($p < 0.005$). The maternal : fetal concentration ratios for the treated pairs were similar to those reported previously. However, the digoxin concentrations in fetuses whose mothers received digoxin (Cases 11 to 14) did not differ from the digoxin-like immunoreactive substance measured in those fetuses with similar problems whose mothers had not received digoxin (Cases 15 to 18), 0.93 ± 0.41 versus 1.27 ± 0.3 ng/ml, respectively ($p = 0.1452$). One fetus (Case 14) was sampled after the maternal digoxin level had ranged between 1.8 and 2.6 ng/ml for a 72-hour period. The digoxin level of this fetus was only 0.8 ng/ml. An additional fetal specimen obtained after maternal therapy had been discontinued was not significantly different. Fetuses born to women with preeclampsia demonstrated intermediate concentrations of digoxin-like immunoreactive substance (mean = 0.5 ± 0.2 ng/ml). The highest digoxin concentration was found in a fetus without antenatal exposure to exogenous digoxin. The mean digoxin-like immunoreactive substance level of the group comprising all ill fetuses not exposed to exogenous digoxin was 0.86 ± 0.4 ng/ml. There was a significant negative correlation ($R = -0.5079$, $p < 0.01$) between gestational age and digoxin concentration. However, the youngest fetuses were usually the sickest. If one excludes the healthy control fetuses from the correlation analysis, the relationship between gestational age and digoxin-like immunoreactive substance is no longer significant.

Comment

Endogenous digoxin-like immunoreactive substance has been reported in patients with clinical disorders associated with volume expansion such as renal failure, congestive heart failure, and normal pregnancy.[7-12] The substance is for all practical purposes biologically indis-

Table I—Cont'd

Group	Abnormality	Gestational age (wk)	Umbilical vein "digoxin" (ng/ml)	Maternal vein "digoxin" (ng/ml)	Perinatal outcome
16	Nonimmune hydrops secondary to SVT	29	1.1	ND	Converted after delivery with digoxin; subsequent neonatal death; multiple endocardial rhabdomyomas
17	Nonimmune hydrops; hypoplastic left heart; in utero closure of ductus arteriosus	31	1.0	ND	Neonatal death
18	Nonimmune hydrops associated with hypoplastic transverse aorta	24	1.4	ND	In utero death
19	Twin-to-twin transfusion; specimen from recipient, hematocrit = 48%	21	0.8	ND	Delivered at 36 wk after selective feticide of cotwin
20	Twin gestation with amorphic acardiac monster and viable infant	26 31	0.5 0.1	ND ND	Alive but still in hospital; congestive heart failure; massive biventricular hypertrophy; hepatosplenomegaly; polycythemia
21	Complete heart block associated with congenital lupus erythematosus	35	0.6	ND	Alive and well
22	Complete heart block associated with congenital lupus erythematosus	38	0.6	ND	Spontaneous vaginal delivery; permanent pacemaker required

24	Unilateral multicystic, dysplastic kidney	29	0.4	ND	Undelivered
25	Hydrocephalus; fetal anemia of unknown cause	34	0.9	ND	Neonatal death

tinguishable from exogenous digoxin[15] and its measurement highly dependent on the assay technique. Concentrations of digoxin measured by immunoassay in fetuses with cardiac abnormality whose mothers were receiving digoxin were similar to concentrations in fetuses with similar abnormality but who were not exposed antenatally to exogenous digoxin. The digoxin level of the one fetus whose maternal level was >2 ng/ml was lower than that of the control group of ill fetuses and did not change after maternal therapy was discontinued. The cardiac and noncardiac disorders (and the resulting alterations in physiologic characteristics) of these fetuses were similar to those in adults with illnesses associated with increased digoxin-like immunoreactive substance. Further, we confirm a previous report that in fetuses of women with preeclampsia there is a mild increase in digoxin-like immunoreactive substance.[14] Other "stresses" both in utero and after premature delivery lead to an increase in digoxin-like immunoreactive substance.[13, 15] Previous conclusions that these elevations were a reflection of gestational age may be equally explainable on the basis of neonatal illnesses that accompany extremes of prematurity.

Investigations of transplacental passage of digoxin may be divided into two groups on the basis of methodology of assay—immunoassay and radiolabeled drug. Chan et al.[6] measured umbilical vein digoxin concentration by radioimmune assay in 11 healthy fetuses whose mothers were receiving digoxin for a maternal illness. Their finding of a high correlation between fetal and maternal plasma concentrations of digoxin, coupled with our inability to demonstrate digoxin-like immunoreactive substance in most healthy fetuses, strongly supports the premise of transplacental passage

of digoxin under those circumstances. Chan et al. also noted high placental binding of digoxin. Saarikowski[7] administered tritium-labeled digoxin to seven women about to undergo an elective pregnancy termination. He too observed the rapid transfer of digoxin and the high placental binding but also noted low cardiac receptor affinity for digoxin at this stage in gestation. No digoxin transport studies have been performed in a pregnancy involving an ill fetus.

Our studies indicate that the concentration of digoxin-like immunoreactive substance in the serum of fetuses with supraventricular tachycardia or hydrops secondary to a cardiac lesion is high enough to account for all the "digoxin" measured by immunoassay in similar fetuses whose mothers have received digoxin. We note that the initial reports of transplacental digitalization were unsuccessful.[16, 17] These observations coupled with the wide variability in time between digoxin administration and fetal response[7] have led us to conclude that little of the maternally administered digoxin actually crosses the placenta under the pathologic circumstances studied in this investigation. The reason is unknown. We speculate that enhanced digoxin binding by the placenta may occur in these abnormal pregnancies, perhaps secondary to hyperplacentosis, which often coexists. It is also possible that the ill fetus has already achieved maximal stimulation of the digoxin receptors or, as noted in the abortuses, has a relatively low affinity for digoxin. However, two of the fetuses with supraventricular tachycardia who failed to respond to transplacental digoxin in utero did respond at least partially when treated after birth. A third fetus responded to direct fetal digitalization but not transplacental therapy. In either event, our findings suggest that further study on the movement of digoxin across the placenta of an ill fetus is necessary and that a prospective, randomized trial of maternal digoxin therapy is needed before digoxin can be accepted as the treatment of first choice for fetal supraventricular tachycardia.

Scalp heat flux and its relationship to scalp blood pH of the fetus

Rudolf Rudelstorfer, M.D., Georg Simbruner, M.D., Vinay Sharma, M.B., and Herbert Janisch, M.D.

Vienna, Austria

A method for directly assessing the metabolic rate of the fetus for optimal management of labor and delivery is still being studied. Since heat, an end product of metabolism, is dissipated from the fetal surface, we measured the heat flux from the fetal scalp and related it to the pH of fetal scalp blood, a measure of metabolism. In 25 human fetuses at risk of intrapartum hypoxia, after the membranes had ruptured and the cervix dilated to >3 cm, we attached a heat flux transducer, a platelet of 2.5 cm diameter and 1 mm thickness, to the fetal scalp and recorded continuously the heat flux from then until delivery. We also obtained one sample of fetal scalp blood in all patients and two such samples in 13 patients for the analysis of pH. We found a significant correlation between heat flux measured immediatley before the scalp blood sampling (presampling values) and the pH of fetal scalp blood ($r = 0.736$; $n = 18$ presampling values; $p < 0.001$). Out of 13 fetuses with two scalp blood samples, the changes in the scalp heat flux paralleled changes in scalp blood pH in 11. We conclude that fetal scalp heat flux is related to the metabolic condition of the fetus. Measuring scalp heat flux during labor could be developed into a noninvasive method for a continuous and more direct assessment of the fetal metabolic rate. (Am J Obstet Gynecol 1987;157:372-7.)

Key words: Scalp heat flux, scalp blood pH, fetal metabolic rate, intrapartum fetal monitoring

Many techniques are available to monitor the well-being of the fetus and to identify the fetus at risk of hypoxia.[1] However, none of them, neither cardiotocography,[2, 3] invasive assessment of biochemical variables such as pH, Po_2, or Pco_2 in the scalp tissue[4] nor ultrasound determination of umbilical blood flow,[5] yield sufficient information about changes of the metabolic rate required to accurately predict fetal outcome. One common reason for the unsatisfactory performance of these methods is that they assess the metabolic rate only indirectly.

Because an individual's heat production, heat loss, and temperature changes are related directly to metabolic rate, several authors studied temperature gradients between the mother and fetus in animals and humans to improve the assessment of the fetal condition.[6-9]

With the concept in mind that heat, an end product of metabolism, has to be dissipated from the fetal surface, we measured the heat flux from the fetal scalp by means of a heat flux transducer. In a previous study we found that scalp heat flux was significantly lower in asphyxiated than in nonasphyxiated fetuses and that during the last 30 minutes before delivery heat flux values correlated well with the pH of the umbilical cord blood.[10] To study whether heat flux changes were related to changes of pH at any time before delivery, we repeatedly measured scalp heat flux and scalp blood pH in individual fetuses. Establishing such a relationship could lead to a noninvasive, easier applicable method of continuously monitoring fetal metabolic rate.

Patients and methods

Selection criteria and consent. We studied 25 women in labor with a single fetus considered to be at risk of intrapartum hypoxia. These patients were selected according to established criteria indicating an increased fetal risk either before or during labor. Risk factors present before labor started were preeclampsia, maternal age >40 years, maternal drug abuse, fetal growth retardation, postmaturity, and significant staining of amniotic fluid.[11] Risk factors during labor were abnormal heart rate patterns.[12] The study was approved by the Ethic Committee of the University of Vienna Medical School, and informed, oral consent was obtained from all mothers. Important details of the parturients and their offsprings are presented in Table I.

Protocol and apparatus. In each woman we contin-

uously recorded the cardiotocogram and the fetal scalp heat flux and at least once determined the pH of fetal scalp blood and the temperature in the mother's axilla and that of the delivery room.

The fetal heart rate was recorded by means of a spiral electrode and the uterine activity by means of an external transducer, with commercially available cardiotocographs (Hewlett-Packard Co., Palo Alto, California, or Kranzbühler—Scientific Medical Systems Co., Solingen D-5650, West Germany). The fetal scalp heat flux was measured by means of a round heat flux transducer, 25 mm in diameter and 1 mm in thickness (model Ha 15-15-13[C], Thermonetics Corp., San Diego, California). These heat flux transducers, containing thermopile on a thin, heat-conductive platelet, produce a voltage output proportional to the heat flow per unit area and time. The calibration constant describing how much heat flux is required to produce 1 mV is provided by the manufacturer. We checked the calibration constant and accuracy of the heat flux transducer with a calibration device that consisted of a copper block with an electric heating coil, which is described in detail elsewhere.[13] We found that all transducers had an accuracy better than 95% (calibration heat flux versus heat flux derived from the calibration constant and voltage output) and a linear response up to at least 100 W/m^2. The voltage output of the transducer was amplified (Multitherm, Biegler Corp., Mauerbach, Austria) and recorded on either the specially adapted cardiotocograph or a Beckman polygraph R 611 (Beckman Instruments, Inc., Fullerton, California). To ensure proper amplification of the signal, a 0.5 mV signal from a standardized electrical source was fed into the apparatus (and the recorder set) to give a 5 cm pen deflection. Calibrations were performed at the beginning of each study, but when the measuring system proved to be accurate they were performed less frequently.

Table II. Frequency of attachments of heat flux transducers necessary for successful recordings

	Frequency of attachment			
Technique of attachment	*No.*	*Once*	*Twice*	*>Twice*
Introducer and glue	9	9	0	0
Amnioscope and glue	11	6	3	2
Direct, no glue	5	2	1	2

Blood from the fetal scalp was sampled as outlined by Saling[14] and then analyzed by an AVL Gascheck 845 (AVL Coop., Graz A-8010, Austria) with automatic calibration. Fetal scalp blood analysis was used in this study despite the known drawbacks of this method because at present we do not know of any better alternative to repeatedly assess the metabolic condition of the fetus. Axillary temperature of the mother and air temperature of the delivery room were measured by standard mercury thermometers.

We obtained 40 fetal scalp blood samples in the 25 patients: one in 12 patients, two in 11, and three in two.

Attachment techniques. We attached the heat flux transducer to the parieto-occipital region of the fetal scalp after rupture of amniotic membranes in patients with a known risk of fetal hypoxia, when the cervix was dilated >2.5 cm, and in the rest of patients, when the cardiotocogram signaled an emergency and fetal blood gas analysis was indicated. With the heat flux transducer properly attached, we recorded the heat flux until delivery of the fetus. Repeated scalp blood sampling and vaginal examinations were performed with the transducer in place. At every vaginal examination we checked whether the heat flux transducer was attached correctly.

The attachment procedure was modified according to the experience gained during the study. Three practical ways of attaching the heat flux transducer emerged: attachment with glue, using an amnioscope or a special introducer device, and without glue, making use of the pressure that the surrounding tissue exerts on the fetal head.

Using an amnioscope of 40 mm diameter, we dried the scalp with gauze, introduced the heat flux transducer with glue on its surface into the vagina, and attached it to the parieto-occipital region of the fetal scalp, and after removal of the amnioscope we firmly pressed the transducer onto the scalp to ensure good contact.

Because of the inconvenience of the amnioscope we

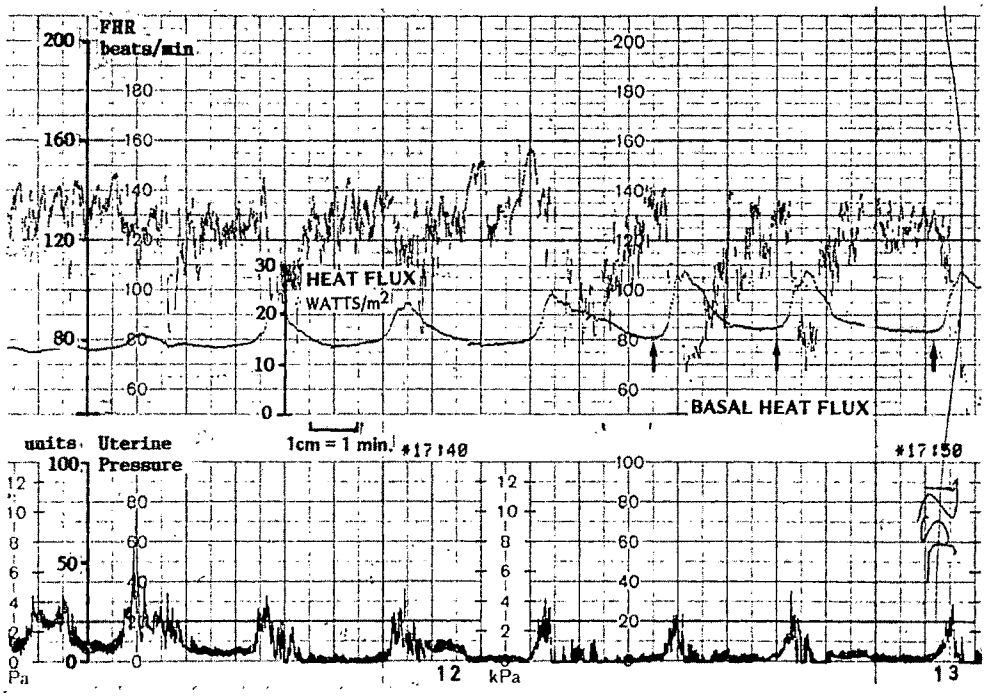

Fig. 1. Original chart of an HP-8040A cardiotocograph monitoring heart rate *(FHR)*, heat flux, and uterine pressure in a fetus with variable and overlapping declerations. Note the characteristic increase of heat flux during contractions. Basal heat flux was measured just before the onset of the next contraction.

developed a special "introducer," a lid that covers the side of the heat flux transducer where the glue is applied. It allows unhindered insertion to the site of attachment. The transducer is then slid out of its protective cover onto the fetal scalp.

For both techniques of attachment we used a water-resistant silicone adhesive (approved for use in humans; 355 Medical Adhesive, Dow Corning, Europe Inc., Brussels, Belgium). Unlike Histacryl, this adhesive absorbs heat during its binding process, has a good gluing power, and is removed easily by acetone.

In five of 25 patients we applied the heat flux transducer to the fetal scalp without glue during a vaginal examination. The transducer was inserted between the fetal scalp and the surrounding tissues during a pause of contractions and usually remained in place because of the tissue forces exerted on it. With this attachment procedure, the position of the transducer was checked more frequently by vaginal examinations.

Independent of the technique of attachment, a dislocation of the heat flux transducer was suspected when the heat flux fell to half of its previous value within a minute, the heat flux no longer varied with contractions (Fig. 1), and gentle pulling on the transducer cable was no longer met with resistance. Correct placement or dislocation was then confirmed by vaginal examination. The numbers of attachment of the heat flux transducer required for a successful recording of heat flux depended on the technique of attachment (Table II).

Analysis of data. One of the authors (V. S.), unaware of the purpose of the study, analyzed the data to avoid any bias. He identified the beginning and end of all procedures that cause artefacts in the recording of heat flux (e.g., vaginal examination, scalp blood sampling, and attachment of transducer). He then discarded these recordings and the recordings of 5 minutes after the end of such a procedure. From artefact-free recordings, the basal heat flux values before and after the fetal scalp blood sampling were then determined. Basal heat flux is the heat flux just before the onset of a contraction during which heat flux distinctly increases or decreases (Fig. 1). The onset of a contraction was identified either from the uterine pressure tracing or directly from the heat flux tracing.

Scalp heat flux values before and after the fetal scalp blood sampling (i.e., presampling and postsampling values) were used for the analysis. To study the interindividual relationship between scalp heat flux and fetal scalp blood pH, we exclusively used the one presampling value closest to delivery.

To examine the intraindividual relationship between scalp heat flux and fetal scalp blood pH, we used data pairs from patients whose pH was measured twice. If available, two presampling values and, if not, a presampling and a postsampling value were taken for analysis. To know whether presampling and postsampling heat

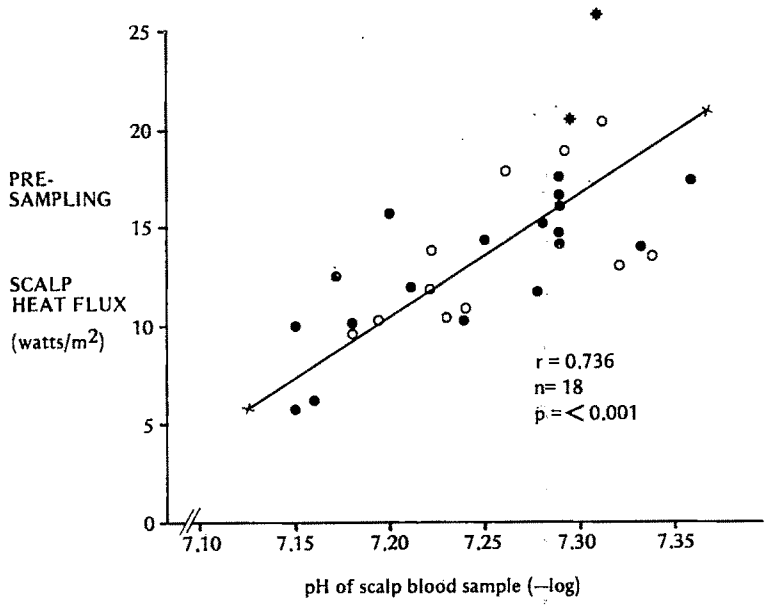

Fig. 2. Diagram shows the interindividual relationship between presampling heat flux values and scalp blood pH. Heat flux values chronologically closest (●), farther away (○), and farthest away (*) from delivery are shown.

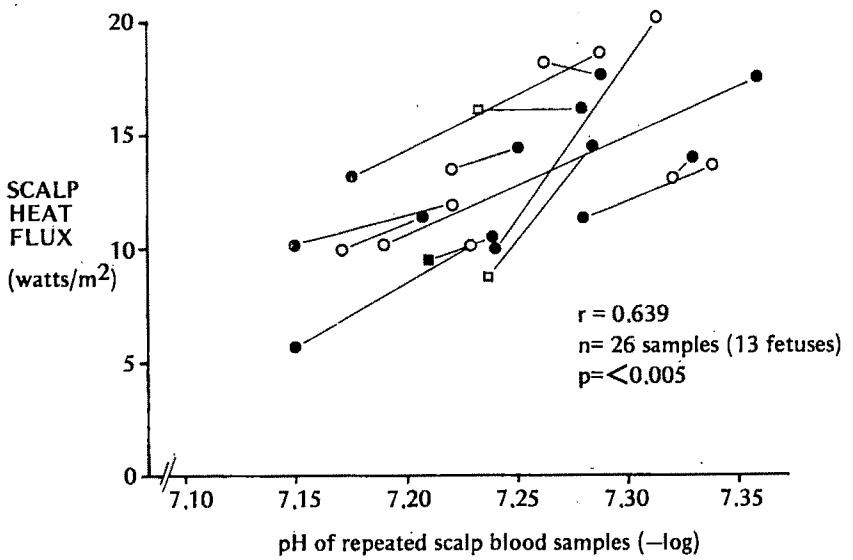

Fig. 3. Diagram shows the relationship of repeated measurements in individuals (i.e., intraindividual relationship). Presampling values chronologically closest (●) and farther away (○) from delivery and postsampling values chronologically next (■) and farther away (□) from delivery.

flux values were exchangeable, we also related both variables to each other.

Statistical analysis. Data are reported as means ± 1 SD. For statistical evaluation we performed a linear regression analysis.

Results

In 18 fetuses with presampling heat flux values, the scalp heat flux correlated significantly with the scalp blood pH ($r = 0.736$; $n = 18$; $p < 0.001$; $y = 41x - 284.5$) (Fig. 2). For each 0.1 decrease of scalp blood pH, scalp heat flux decreased approximately 5 W/m² within the range of pH 7.15 to 7.35.

Out of 13 fetuses with measurements on two occasions, changes of scalp heat flux paralleled changes of scalp blood pH in 11. In one fetus the scalp heat flux remained constant and in another it increased slightly despite a small decrease in scalp blood pH (Fig. 3).

Changes in scalp heat flux reflected increases and decreases in scalp blood pH equally well.

In 20 cases, in which presampling and postsampling heat flux values were obtained, presampling heat flux correlated statistically significantly with postsampling heat flux values ($r = 0.815$; $n = 20$; $p < 0.001$; $y = 2.556x + 0.803$). The mean difference between the two variables was 0.2 W/m² with an SD of ±0.2 W/m². Therefore, presampling and postsampling heat flux values were considered to be equally representative for actual scalp heat flux.

In 25 patients with either presampling or postsampling heat flux values the correlation between scalp blood pH and scalp heat flux was also statistically significant ($r = 0.771$; $n = 25$; $p < 0.001$; $y = 63.7x - 447.9$).

Comment

The results of this study indicate that the heat flowing from the fetal scalp is related to the metabolic condition of the fetus assessed as pH of the fetal scalp blood. These results agree with a previous study of similar nature in which the heat flux from the fetal scalp before birth was found to correlate with the pH of the umbilical arterial blood at birth.[10]

For measuring the scalp heat flux, the following conditions have to be met: First, the head has to be the presenting part and should be engaged, because a floating head does not allow sufficient pressure to be applied for the attachment. Second, the cervix has to be dilated to >3 cm for the introduction of a 25 mm diameter transducer. Smaller transducers (e.g., 10 by 20 mm) would allow attachment at a cervical dilatation <3 cm, but they are less accurate. Third, the membranes have to be ruptured for the transducer attachment with glue. However, heat flux measurements are possible with intact membranes if the head is firmly engaged in the birth channel, no glue is used, and the transducer is held in place by the tissue forces exerted on it. Fourth, some cooperation from the patient is required for the attachment of the transducer, especially when an amnioscope is used. With the special introducer, the attachment procedure does not differ essentially from the one of a spiral electrode. Fifth, attachment of the transducer with glue seems advantageous (Table II). The use of the special introducer and glue, according to our experience so far, provides satisfactory and secure attachment of the heat flux transducer with a low failure rate. However, more experience is required to accurately assess which attachment technique is optimal for which condition and which criteria other than vaginal examinations are reliably indicating the firm attachment of the transducer.

Despite a highly significant correlation between scalp heat flux and scalp blood pH, the absolute values of heat flux were somewhat scattered around the regression line (Figs. 2 and 3). Two factors could be responsible for this: heat flux is measured at only one site of the scalp and may vary with the position of the transducer on the scalp, and the temperature of the birth channel could be responsible for the variation of absolute heat flux from fetus to fetus. In the mothers studied axillary temperature ranged from 36° to 37.5° C and remained fairly constant during the time of study. The differences in the axillary temperature were large enough to be responsible for the variation in absolute heat flux on one hand but certainly small enough not to disturb the good correlation between changes in heat flux and changes of pH. For further studies we advocate measurement of the environmental temperature of the head (i.e., the temperature of the maternal soft tissue of the birth channel) and correlation of heat flux values to it.

For lack of a better method to assess the metabolic rate of the fetus repeatedly, we used the pH of the fetal scalp as a reference parameter. We were aware of the critique and limitations of this method.[14, 15] Despite all methodic drawbacks of fetal scalp blood analysis, correlations between both variables investigated were surprisingly good.

The decrease in scalp heat flux with the occurrence of metabolic acidosis (i.e., partly anaerobic metabolism) could be the result of a decreased metabolic heat production of the underlying brain or an increased circulatory heat convection out of the brain or both. Simbruner et al.[16] found that the heat flux from the head is decreased in microcephalic and hydrocephalic newborns, known for decreased cerebral heat production, and increased in children with hypoplastic left heart syndrome, known to have decreased cerebral circulation, compared with normal newborns in a similar thermal environment. Apart from metabolic heat production of and circulatory heat convection out of the brain, other factors such as scalp perfusion, reduced by acidosis, could cause the heat flux to decrease. Further studies are required to elucidate the thermal physiology of the fetal and neonatal head under pathophysiologic conditions.

From the practical point of view, monitoring the fetal scalp heat flux offers several advantages. Unlike fetal scalp blood sampling, the method is noninvasive (i.e., the scalp remains intact), safe, and technically simple and yields continuous information related to the metabolic heat production of the fetus. In contrast to cardiotocography, in which hypoxia via the autonomous nervous system alters the fetal heart rate and signals danger, in this method the measured variable is heat flux and thus is directly related to metabolism. Consequently, measuring heat flux together with cardiotocography has the potential to sort out signals of danger

from true events of hypoxia and thus to reduce the number of false positive predictions of fetal distress often followed by unnecessary surgical interventions.[1]

In conclusion, the described method and reported correlation between scalp heat flux and fetal scalp blood pH could be a first step toward a more precise system of monitoring fetal metabolic rate.

Neonatal seizures after cesarean delivery: Higher risk with labor

William N. Spellacy, M.D., Paul Q. Peterson, M.D., Ann Winegar, M.S., and Edward J. Quilligan, M.D.

Chicago, Illinois, and Davis, California

A study was done on the occurrence of neonatal seizures in 14,367 infants delivered by cesarean section in a perinatal region in 4 years. Although seizures occurred in 1% of all of these infants, small infants weighing <2500 gm at birth had the highest frequency (>4%). Term infants delivered before labor (repeat cesarean section) had the lowest seizure rate (<0.2%), and this was a significantly lower (four times) frequency than that seen in term infants delivered by primary cesarean section. These data suggest that brain function as indexed by neonatal seizures can be adversely affected during labor. (AM J OBSTET GYNECOL 1987;157:377-9.)

One of the most serious perinatal problems today is infant brain damage that may leave a child impaired for life. In some neonates an early symptom of lifetime impairment is seizures.[1] Controversy exists as to when brain damage actually occurs in infants. Some studies suggest that it may occur during pregnancy before labor begins.[2] This study was undertaken to determine

if there was a statistical difference between the incidence of neonatal seizures in infants delivered by elective cesarean section (no labor) and infants delivered by primary cesarean section (with labor). Infants weighing <2500 gm at birth were analyzed separately from other infants because low birth weight has such a significant impact on the occurrence of seizures, as this study will again demonstrate.[1]

Methods

The University of Illinois Perinatal Network began to electronically monitor the quality of care by abstracting all maternal and infant outpatient and hospital charts in 1982.[3] Information from approximately 17,000 deliveries per year is entered into the data base. This study includes information from 14,367 cesarean sections performed from 1982 through 1985, which represented 21.1% of the total of 68,143 deliveries during that period. In that total, 357 infants were diagnosed as having seizures (0.5%), whereas in the total cesarean section population 146 infants or 1.0% were diagnosed with seizures.

Of the total of 8783 infants delivered by primary cesarean section, 116 were diagnosed with seizures (1.3%); of the total of 5584 infants delivered by elective cesarean section, 0.5% or 30 infants were diagnosed with seizures. All analyses in the study were performed by χ^2 incorporating Likelihood Ratio, Continuity Adjusted, Mantel-Haenszel, and Fisher's exact test (one and two tail).

Results

The results of the study are shown in Tables I and II. The repeat cesarean section group was further divided into a low-risk group who had no antepartum problems such as hypertension, bleeding, and diabetes and were delivered electively without labor only because of a prior cesarean section history. Neonatal seizures were more common in small infants but the proportion of seizures was similar between primary, repeat, and low-risk repeat cesarean sections for infants whose birth weights were <2500 gm (4.8% versus 4.1% versus 3.6%; p not significant). The frequency of seizures in infants weighing >2500 gm is shown in Table II. There are significantly fewer infants with seizures in the repeat cesarean section group ($p < 0.000$); for the repeat cesarean sections the difference is three times (0.64% versus 0.21%) and for the low-risk repeat cesarean section group the difference is 4.3 times (0.64% versus 0.15%).

When comparing the differences of incidence of seizures by the two birth weight categories the percent of seizures was eight times higher in the small infants than in the large infants when primary cesarean section was the mode of delivery, although the percent of seizures was 21 times higher in small infants than in the large infants when repeat cesarean section was the mode of delivery. Thus the risk of seizure was one in 446 for term neonates delivered by cesarean section without labor, one in 156 for term infants delivered by cesarean section after onset of labor, and one in 667 for term infants of low-risk mothers who had routine repeat cesarean sections.

Comment

An understanding of the factors associated with an increased frequency of neonatal seizures may provide new information about other forms of perinatal morbidity and may allow a modification in perinatal care to reduce these forms of central nervous system damage.

In this study, as well as others, prematurity was a

significant risk factor.[1] This study also analyzed the effects of labor by studying the differences in frequency of seizures in infants delivered by elective repeat and primary cesarean sections. The repeat cesarean section group was further analyzed by comparing the subgroup that had no antepartum risk factors. In this low-risk group an elective repeat cesarean section was done and their neonates had the lowest risk of seizures (0.15%). When antepartum risk factors were present in the repeat cesarean section group, such as diabetes mellitus and hypertension, the neonatal seizure rate increased only slightly to 0.21%. Women who had labor and then underwent a cesarean section had the highest frequency of neonates with seizures (0.64%). These data suggest that labor rather than antepartum diseases is the risk factor for neonatal seizures and presumably central nervous system damage. This important finding suggests that additional studies are needed to determine when the function of the central nervous system of the infant is altered by the labor process itself.

We gratefully acknowledge the assistance of Larry Seifert, M.S., in the statistical analysis of the data. The data provided for the study belong to the members of the University of Illinois Perinatal Network and were used with their permission.

Primary cesarean section and subsequent fertility

Anita Parnes LaSala, M.D., and Alan S. Berkeley, M.D.
New York, New York

The incidence of infertility after primary cesarean section (study group) was compared to an age- and parity-matched control group who underwent vaginal delivery during 1978 at The New York Hospital. Secondary infertility occurred in 17/291 (5.8%) of the study group and 5/279 (1.8%) of the control group ($p<0.03$). Excluding those who practiced contraception and those who underwent sterilization, this difference is still significant ($p<0.02$). Excluding those patients with a history of infertility prior to the 1978 birth, there was still a trend to increased subsequent infertility in the cesarean section group although this difference did not reach statistical significance ($p<0.06$). The patients with infertility did not have a higher incidence of postpartum endomyometritis, prolonged rupture of the membranes, or abnormal placentation. The causes of the secondary infertility could not always be directly related to cesarean section; the concept of an "infertility threshold" will be discussed. (AM J OBSTET GYNECOL 1987;157:379-83.)

Key words: Cesarean section, secondary infertility, "infertility threshold"

The rate of cesarean delivery has increased dramatically over the last 15 years. Although the benefits of this trend for the unborn child have been widely debated, the maternal effects have been less thoroughly investigated. With modern blood-banking and anesthesia and with the widespread use of prophylactic antibiotics, immediate postoperative morbidity for cesarean section has decreased and death is extremely rare. Long-term maternal morbidity has been less fully examined.

The incidence of secondary infertility is unknown; its cause is diverse and in many cases unexplained. The most commonly accepted cause of secondary infertility is tubal damage and adhesions that occur after pelvic inflammatory disease[1]; the role of other causes of peritonitis is less clear-cut.[2] Three studies have failed to indicate an association between induced abortion and subsequent infertility.[3-5] Abdominal myomectomy, while frequently performed as a treatment for infertility, has also been suggested as a cause of infertility in previously fertile women.[6, 7] Endometrial ossification

Table I. Derivation of study groups

	Cesarean section	*Vaginal delivery*
Initial No. of charts requested	502	502
Eligible, chart available	439	442
Lost to follow-up	108	127
Inadequate follow-up	40	36
Complete follow-up	291 (66.3%)	279 (63.1%)

following retained products of conception and inadvertent tubal division at the time of inguinal herniorrhaphy have also been reported as rare causes of secondary infertility.[8, 9]

The relationship of cesarean section to subsequent infertility has remained largely unexplored, although it has been postulated that postoperative endomyometritis, pelvic adhesions, and uterine cavity damage might be possible mechanisms.[10] Two recent studies have failed to document a relationship between postoperative endomyometritis and secondary infertility[11, 12]; these studies, however, used uninfected cesarean section patients as the control poulation. This study was designed to compare the incidence of infertility after cesarean section to that of an age- and parity-matched control group who underwent vaginal delivery.

Material and methods

The name and hospital number of each patient who underwent primary cesarean section at The New York Hospital in 1978 were retrieved from the daily obstetric logbook; the name and hospital number of the next age- and parity-matched patient who was delivered vaginally were also obtained. The hospital record was requested for all patients; outpatient records were reviewed and personal contact was attempted in all patients whose fertility status was still unclear after review of the inpatient chart.

Patients were considered ineligible for the study if their hospital records were unavailable or incomplete or if they underwent sterilization during the same hospitalization. Charts were reviewed for demographic data, labor and delivery events, postpartum course for mother and infant, and any history of previous infertility; the chart was also searched for any subsequent admission or information regarding future reproductive events. Even if the hospital chart was available and complete, a patient was considered "lost to follow-up" unless there was a contact with reproductive information more than 3 years after delivery; patients with a reproductive event at any time after the 1978 delivery were considered to be evaluable. All subsequent infertility was documented by medical record or personal contact with the patient by one of the authors (A. P. L.). These patients had not conceived as of January 1984 and had been trying to do so for at least 2 years.

Table II. Differences in incidence of postpartum endomyometritis between those patients lost to follow-up and those in both the study and control groups

Group	*Endomyometritis*		*Significance*
	n	%	
Cesarean section (study group)	81/291	27.9	$p < 0.005$
Cesarean section (lost to follow-up)	66/148	44.6	
Vaginal delivery (control group)	2/279	0.7	$p < 0.005$
Vaginal delivery (lost to follow-up)	9/163	5.5	

Standard febrile morbidity was defined as the presence of a temperature > 38° on at least two occasions 6 hours apart more than 24 hours after delivery. Endomyometritis was defined as the presence of standard febrile morbidity, administration of antibiotics, diagnosis documented on the chart, and absence of any other source of fever.

The χ^2 analysis with Yates' correction was used to test the significance of the data.

Results

The 502 patients who underwent primary cesarean section at The New York Hospital in 1978 constituted the study group; a like number of patients who underwent vaginal delivery constituted the control group. Table I demonstrates how many patients in each group were ineligible, were lost to follow-up, or had inadequate follow-up. Complete follow-up was available for 291/439 (66.3%) of the study group and 279/442 (63.1%) of the control group; this meant that they either had an intrauterine pregnancy at some time since delivery, were using birth control at least through 1981, or had at least 2 years of secondary infertility.

There was no significant difference between those patients lost to follow-up and those who were evaluable in terms of age, race, parity, socioeconomic status, indication for cesarean section, type of vaginal delivery, or duration of previous infertility. There was, however, a significantly higher incidence of postpartum endomyometritis in those patients lost to follow-up (Table II).

Demographic data for the two groups are presented in Table III. Those who underwent cesarean section

Table IV. Subsequent reproductive outcome in study and control groups

Outcome	*Cesarean section (n = 291)*	*Vaginal delivery (n = 279)*
Viable infant	171	183
Sterilization*	7	3
Contraception*	64	52
Elective abortion†	19	26
Spontaneous abortion†	13	10
Ectopic pregnancy†	1	1
Infertility	16	4

*No intervening pregnancy.
†Only reproductive event.

had a higher incidence of previous infertility and primiparity than those who underwent vaginal delivery ($p<0.05$) and were more likely to be private patients ($p<0.01$).

Subsequent reproductive outcome is documented in Table IV. For statistical purposes those patients whose only reproductive event was an ectopic pregnancy were classified as infertile. Therefore the incidence of infertility was 17/291 (5.8%) in the study group and 5/279 (1.8%) in the control group, a significant difference ($p<0.03$). If one excludes those patients using contraception or having undergone sterilization and includes only those at risk for pregnancy, the incidence of infertility was 17/220 (7.7%) in the study group and 5/224 (2.2%) in the control group, also a significant difference ($p<0.02$). If one includes those patients who had only spontaneous abortions in the infertility category, the incidence of infertility becomes 30/220 (13.6%) in the study group at risk for pregnancy and 15/224 (6.7%) in the control group, also significantly different ($p<0.02$).

Table V compares the incidence of certain factors that might be related to subsequent infertility between those patients with subsequent infertility and those without in both groups; this includes history of previous infertility, occurrence of infection, length of ruptured membranes, and indication for cesarean section. Significantly more patients who had infertility after cesarean section had a history of infertility prior to that delivery compared with those who did not have infertility after cesarean section ($p<0.05$). If all patients with a history of previous infertility are excluded from our analysis, 13/204 (6.4%) of those who underwent cesarean section developed secondary infertility compared with 5/224 (2.2%) of those who had a vaginal delivery; a stong trend for secondary infertility after cesarean section persists although it does not quite reach statistical significance ($p<0.06$).

Table VI documents the causes of the subsequent infertility, if known, in both groups.

Comment

Despite the difficulties inherent in obtaining long-term follow-up in a mobile, urban population, a substantial number of patients (64.7%) were completely evaluable by our criteria. Those lost to follow-up were different from those included in the study in only one respect, namely, their higher incidence of endomyometritis. Although suggested as a possible cause of subsequent infertility, the effect of postpartum endomyometritis has been discounted both by our own data (those with subsequent infertility after cesarean section had a lower rate of postpartum endomyometritis than those with established fertility after cesarean section) and by two recent studies.[11, 12] In fact, if postpartum endomyometritis were a cause of subsequent infertility, then our study is underestimating post–cesarean section infertility because the number of cesarean section patients lost to follow-up includes many more with postpartum endomyometritis than those lost to follow-up in the vaginal delivery group. Therefore the conclusions drawn from our study population are valid.

Secondary infertility was found significantly more frequently in those patients who underwent cesarean section. The patients with infertility did not have a higher incidence of postpartum endomyometritis, prolonged rupture of the membranes, or placental abnormalities when compared with those without subsequent infertility. However, in the control group the absolute incidence of secondary infertility was extremely low (2.2%); on a population basis the 7.7% reported for the study group would, if confirmed, represent a dramatic increase in infertility related to cesarean section. Of further interest, the rate of secondary infertility for our entire population was 22/484 (4.5%). However, our cri-

teria and methodology probably cause us to underestimate the incidence of secondary infertility in all groups. This is because we used 2 years rather than the more standard 1 year as our definition of infertility and because infertility patients are less likely than maternity patients to be hospitalized, making them more likely to be lost to follow-up.

Infertility can be a multifactorial problem. It is possible that woman with one or more minor abnormalities of reproductive function can still become pregnant if the sum of the effects of these abnormalities falls below some "infertility threshold." The added stress of a cesarean section (peritubal adhesions or intrauterine injury) may push these women over the threshold and result in subsequent infertility. One could argue that patients with a history of previous infertility should be excluded from calculations of the rate of secondary infertility after cesarean section because it is difficult to assess how much of this secondary infertility can be attributed to the mode of delivery and how much to a preexisting fertility problem. However, we do not believe that exclusion of these patients is either necessary or appropriate, because the definition of "previous infertility" used in this study is very broad. We included in this category any patient who ever had an infertility workup, with or without a diagnosis being established.

Of the 17 patients with infertility after cesarean section, four are said to have previous infertility. Two of these women started a fertility evaluation, underwent normal hysterosalpingography, had no further workup, and conceived. One woman stated that she had a "hormonal imbalance" discovered after a workup that included normal semen analysis and hysterosalpingography; she was treated with a progestational agent for 5 days and conceived. This "therapy" was repeated, unsuccessfully, after cesarean section when she again complained of infertility. The last patient conceived with the help of clomiphene citrate and insemination with sperm of her husband. After the cesarean section, this therapy, as well as human menopausal gonadotropin therapy, was tried without success. In reality, although included in our calculations, the first three patients had no cause of infertility identified before cesarean section. The fourth patient had an ovulatory problem successfully treated with medical therapy prior to operation that failed to respond to the same, and more intensive, therapy after operation; this suggests that an additional factor had come into play. Any increase in the rate of secondary infertility caused by the inclusion of these patients in our statistics only serves to confirm our thesis that cesarean delivery causes patients with marginal fertility to become infertile.

This concept of a threshold is important because only

four of our 17 study patients with infertility had verified tubal or intrauterine disease as the sole cause of infertility. Most authorities would accept that these abnormalities resulted from operation. The other 13 patients had a cause that either was not clearly directly related to cesarean section or was as yet unknown. It is in these patients that surgically related subclinical injury may have an additive effect to other nonsurgical infertility factors that may have knowingly or unknowingly been present before the cesarean section. This threshold concept may explain the paradox of increased infertility after cesarean section unexplained by obvious postsurgical morbidity.

Asherman's syndrome is a rare occurrence after cesarean section without curettage.[13, 14] Nevertheless, two of the patients in our study group suffered this complication and required hysteroscopic division of intrauterine synechiae. One has subsequently had an ectopic pregnancy and the other has as yet failed to conceive.

Two recent epidemiologic studies addressed the issue of the effect of cesarean section on subsequent fertility. Zdeb et al.[15] demonstrated an 11% decrease in subsequent pregnancies in women who had undergone primary cesarean section as compared with those who had a vaginal delivery. It could not be determined from this study whether this was a voluntary difference. Hemminki et al.[16] came to a similar conclusion; however, patients undergoing surgical sterilization were not excluded from the data, and there were more of these patients in the cesarean section group. Our study addresses both these issues by excluding women who were practicing contraception or had undergone sterilization. We suggest that the difference in fertility is not voluntary; there is a significantly higher incidence of infertility after cesarean section among women desiring pregnancy. If confirmed by future investigations, this information will have to be added to the other components of the risk-benefit equation for primary cesarean section.

A study on intrauterine fetal resuscitation with terbutaline

Michael S. Patriarco, D.O., Bruce M. Viechnicki, M.D., Thomas A. Hutchinson, M.D., Stephen K. Klasko, M.D., and Sze-Ya Yeh, M.D.

Allentown, Pennsylvania

A randomized study on the effect of terbutaline on fetal distress was carried out in 20 patients who showed evidence of ominous fetal heart rate patterns and fetal scalp blood pH values of <7.25. Of those, 11 received terbutaline (study group) and nine did not (control group). There was a significant improvement in the acid-base status of the fetus in the study group compared with those in the control group ($p < 0.01$). No significant maternal or fetal morbidity occurred in the study group. Apgar scores at 1 minute were 7 or greater in 10 of the 11 study subjects whereas only four of the nine control subjects had a score of 7 or greater. These results suggest that terbutaline may become a useful agent in the treatment of intrauterine fetal distress. (Am J Obstet Gynecol 1987;157:384-7.)

Key words: Terbutaline, fetal distress, fetal resuscitation

Recent advances in continuous electronic fetal heart rate monitoring and fetal capillary blood pH measurements have facilitated the detection of fetal distress in utero; however, the treatment of fetal distress has remained relatively unchanged during the last two decades. Acute fetal distress, when indicated by ominous fetal heart rate patterns or acidotic fetal capillary blood, requires prompt intervention. If no relief occurs with conventional methods (i.e., changing the maternal position, oxygen administration, and discontinuation of oxytocin if it is in use), immediate delivery should be considered by either cesarean section or rapid operative vaginal delivery.

When immediate cesarean delivery is indicated, the time interval required to prepare for the surgery may be too long for an already-compromised fetus. Therefore, any intermediate treatment that could prevent further deterioration of the fetal condition would be very useful.

Caldeyro-Barcia et al.[1] first described the potential use of a pharmacologic agent for intrauterine resuscitation. In their study a β-sympathomimetic agent, metaproterenol sulfate, was used. By decreasing uterine activity through β-sympathomimetic activity, uterine perfusion to the fetus could be increased, thereby improving its acid-base status. Pharmacologically, the advantages of using this agent for intrauterine resuscitation are manyfold: first, the rapid pharmacologic effect demonstrated by this agent; second, increased maternal venous return, stroke volume, and cardiac output as a result of its vasodilating effect (this increase results in improvement of the uteroplacental blood flow[2, 3]); third, increased cardiac output and uteroplacental blood flow caused by maternal tachycardia and sympathetic activity[2, 3]; fourth, increased uteroplacental blood flow caused by the β-sympathomimetic agent[4-8]; and fifth, enhanced transfer of glucose from the mother of the fetus because of maternal hyperglycemia caused by this agent.[3]

Because of the limited number of published articles studying the issue of intrauterine resuscitation, this prospective, randomized study was undertaken to evaluate terbutaline, a β-sympathomimetic agent, for the management of intrapartum fetal distress.

Material and methods

This study was carried out in the labor and delivery suite at the Allentown Hospital from January 1984 to December 1985. When patients in labor showed signs of fetal distress as indicated by repetitive late decelerations or severe variable decelerations with internal fetal heart rate monitoring, they were managed initially with conventional methods (i.e., administrating oxygen to the mother by mask, changing maternal positions, placing her in the Trendelenburg position when needed, and discontinuing oxytocin infusion if it was in use). If fetal heart rate deceleration patterns persisted despite the above measures, a fetal scalp blood sample was obtained, and the pH was measured with a blood gas analyzer (Instrumentation Laboratory, Inc., Lexington, Mass.). If the pH value was below 7.25, which indicated fetal distress,[9] the patient was selected for the study after a proper informed consent was obtained. She was then randomly assigned to the study or the control group by randomly generated numbers. While preparations were being made for delivery the patients in the study group were given 0.25 mg terbutaline sulfate injection subcutaneously, and those in

the control group received no medication. Fetal heart rate monitoring was continued in both groups until the infant was delivered. At the time of delivery, blood samples were obtained from the umbilical artery in heparinized syringes for pH determinations. Immediately after delivery, all neonates were evaluated by a pediatrician or neonatologist in the delivery room and Apgar scores were given.

Twenty pregnant patients were selected for this study. Eleven patients were randomized as the study group and nine as the control group. A separate t test was used to compare the pH values and a χ^2 test was used to compare the Apgar scores in two groups. A p value <0.05 was used to indicate significant differences.

Seven additional cases are presented for discussion. They were not included in the study because a fetal scalp blood sample was not obtained before administration of terbutaline because of urgent situations that required immediate intervention.

Results

Table I lists the demographic data in both groups. These include the maternal age, parity, gestational age, complications of pregnancy, and type of anesthetic used for delivery. There was no significant difference found between the groups.

Of the 11 patients in the study group, seven demonstrated fetal distress as indicated by late decelerations whereas the remaining four patients had severe variable decelerations. After terbutaline administration, five patients demonstrated complete cessation of uterine activity whereas the remaining six patients showed diminished frequency of contractions. In all five patients in whom uterine activity subsided, no further fetal heart rate decelerations were noted. Five of the six remaining patients continued to have fetal heart rate decelerations at a lesser degree of amplitude and frequency. Only one patient did not show any improvement in the fetal heart rate deceleration patterns.

Of the nine patients in the control group, six showed repetitive late decelerations and three had severe variable decelerations. In all instances no improvement was noted in the fetal heart rate deceleration patterns or the uterine activity before delivery.

Fig. 1 and Table II summarize the changes of blood pH values in both the control and study groups. In the control group the mean fetal scalp blood pH was 7.18 with an SEM of 0.02. In the study group the mean fetal pH was 7.15 with an SEM of 0.02. The difference of means between these two groups was not significant. The mean umbilical arterial blood pH in the control group was 7.17 with an SEM of 0.02, whereas the mean umbilical artery pH of the study group was 7.25 with an SEM of 0.03. This difference was statistically significant at $p < 0.025$. In 10 of the 11 treated patients the umbilical artery pH was greater than the fetal capillary blood pH. In six of the nine patients in the control group the umbilical artery pH was actually lower than the last fetal pH value. A t test was performed to compare the mean of the fetal capillary blood pH with the

≥7	10	5	
5 min Apgar score			
<7	0	2	NS
≥7	11	7	

*p Values were obtained from the χ^2 test.

mean of the umbilical artery pH in both groups. The umbilical artery mean pH was found to be significantly higher than the fetal scalp blood pH in the study group ($p < 0.01$), whereas there was no statistical difference in the control group.

Ten of the 11 patients in the study group had 1-minute Apgar scores of 7 or greater. However, in the control group only four of the nine patients had 1-minute Apgar scores of 7 or greater. This difference was statistically significant at $p < 0.025$ (Table III).

There were no perinatal deaths in either group. The mean birth weight in the study group was 7 pounds 2 ounces with a range of 4 pounds 8 ¾ ounces to 9 pounds 4 ¾ ounces. The mean birth weight in the control group was 7 pounds 5 ounces with a range of 4 pounds 15 ¾ ounces to 9 pounds 2 ounces. There was no apparent difference in neonatal morbidity in either group.

There were no maternal side effects noticed as the result of terbutaline administration. A mild tachycardia was noted in patients who received medication; however, they remained symptom free at all times.

All patients in this study were delivered by cesarean section. Nine of the 11 patients in the study group were delivered under general anesthetic, one under spinal anesthetic, and one under epidural anesthetic. In the control group, six of the nine patients were delivered under general anesthetic, one under epidural anesthetic, and two under spinal anesthetic.

In the seven additional patients presented, who did not meet protocol requirements, five were delivered by cesarean section and two were delivered vaginally. Both of the patients delivered vaginally had prolonged fetal bradycardias lasting 7 minutes or longer that did not respond to oxygen administration, positional changes, or discontinuation of oxytocin. While preparing for cesarean section, terbutaline was administered subcutaneously. Within the next 5 minutes the fetal heart rate returned to normal. Both patients were allowed to continue labor and had successful vaginal deliveries. The remaining five patients had urgent situations that required immediate delivery. There was not sufficient time to obtain a scalp blood sample for pH determination before cesarean section. All patients received terbutaline before surgery. The umbilical artery blood pH was >7.25 in three of these five patients. Four of the five patients had a 1-minute Apgar score of 7 or greater.

Comment

Once detected, fetal distress has traditionally been treated by giving oxygen, changing maternal positions, or discontinuing oxytocin infusion. If there is no apparent improvement in the fetal status indicated by the fetal scalp blood pH, or the fetal heart rate tracing, prompt delivery should be considered.

In 1969 Caldeyro-Barcia et al.[1] described a potential new method for the treatment of fetal distress. In this study, metaproterenol sulfate, a β-sympathomimetic agent, was administered through a continuous intravenous infusion. In this report, fetal scalp blood samples were obtained for pH determination sequentially after the initiation of metaproterenol sulfate infusion until the fetal pH recovered to 7.30 or greater. Once the patient had recovered, the infant was delivered by cesarean section in a "resuscitated state." Most of the subsequent studies on this subject were done in foreign countries.

In this country, Arias[10] attempted to manage acute intrapartum fetal distress with terbutaline administration. Fifteen pregnant women in whom fetal distress was detected by electronic fetal heart rate monitoring who did not respond to maternal positional changes, oxygen administration, or discontinuation of oxytocin received terbutaline, 0.25 mg, subcutaneously or intra-

venously. All patients showed evidence of partial or total fetal recovery after the drug administration. However, this study did not provide a biochemical evidence of fetal recovery.

Tejani et al.[11] also used terbutaline for intrauterine fetal resuscitation. Eighteen patients were selected for the study with the criteria of fetal distress defined by fetal acidosis (fetal scalp blood pH <7.25).[9] Ten of the 18 patients received terbutaline. There was an obvious improvement of fetal heart rate patterns and fetal acid-base status when fetal scalp pH was compared with the umbilical artery pH in these treated cases. Although this was not a randomized study, there appeared to be evidence suggesting that terbutaline could be used as a resuscitative agent in utero.

Lipshitz[12] used an intravenous bolus injection of hexoprenaline, another β-sympathomimetic drug, for the treatment of fetal distress in six patients. A rapid improvement in fetal heart rate occurred on all occasions. Again, this study did not provide biochemical evidence of fetal improvement.

In our study, pH was chosen to demonstrate fetal distress because previous studies have indicated a poor correlation between ominous fetal heart rate patterns and the Apgar scores.[1] We have demonstrated a significant improvement of the acid-base status in the neonates of the study group as compared with the control group. This study also showed evidence of better neonatal condition in the study group in terms of Apgar scores. No significant maternal or fetal side effects occurred in any of the patients who received terbutaline.

The results of this study suggest that terbutaline may be useful in the management of fetal distress during labor when other conventional methods have failed. Terbutaline offers several advantages in the management of acute fetal distress. First, terbutaline seems to improve the acid-base status of the fetus immediately and therefore allows delivery of a resuscitated infant rather than a depressed infant. Second, giving terbutaline may decrease the need for immediate delivery. This may be of great benefit, especially in a hospital in which emergency anesthetic coverage is not readily available. Third, since fetal distress may be a transient phenomenon, terbutaline may assist the fetus in overcoming this transient stress and allow the patient to continue labor. Fourth, since terbutaline may decrease the urgency of delivery, additional time may be available for the patient to receive conductive anesthetic, thereby decreasing the additional risks of "crashed" cesarean section and general anesthetic.

We gratefully acknowledge the cooperative effort of the attending and nursing staff of the Allentown Hospital.

A randomized trial of ritodrine tocolysis versus expectant management in patients with premature rupture of membranes at 25 to 30 weeks of gestation

Thomas J. Garite, M.D., Kirk A. Keegan, M.D., Roger K. Freeman, M.D., and Michael P. Nageotte, M.D.

Long Beach, California

Expectant management was compared with similar management plus ritodrine tocolysis in a randomized controlled trial in patients with premature rupture of membranes at 25 to 30 weeks of gestation. In the tocolysis group intravenously administered ritodrine was instituted at the onset of labor and then changed to the oral form if successful. Tocolysis was discontinued or not instituted after 31 weeks of gestation. Seventy-nine patients were randomized over a 4-year period, 39 in the tocolysis group and 40 in the expectant group. Twenty-three patients in the tocolysis group actually received ritodrine. No difference between the two groups was demonstrated in the interval between premature rupture of membranes and delivery or in reaching 32 weeks of gestation. No statistical difference was seen in maternal morbidity. Birth weights and gestational ages at delivery were similar between the two groups as were the incidences of neonatal morbidities caused by prematurity and infection and in the duration of neonatal hospital stays. Despite being conducted in those gestational ages in which prolongation of pregnancy might be expected to be of most benefit, no difference could be demonstrated with the addition of tocolytic therapy over expectant management alone. (Am J Obstet Gynecol 1987;157:388-93.)

Key words: Tocolysis, PROM

Premature rupture of membranes (PROM) is the most common single diagnosis leading to premature delivery and neonatal complications that require admission to a neonatal intensive care unit. Better understanding, newer antibiotics, and improved diagnostic techniques have led to fewer major maternal complications. As a consequence, in recent years there has been an increasing tendency to develop management protocols designed principally to prolong pregnancy and decrease neonatal complications from prematurity.

Premature labor is a natural consequence of PROM, since 80% to 90% of preterm patients will go into labor within a week of membrane rupture.[1] With the availability of effective tocolytic agents it would seem logical to apply this form of therapy to patients with premature labor following PROM. In the past experts have thought that tocolysis was contraindicated in such patients primarily because of the concern of increasing the likelihood of infectious morbidity and mortality.[2] However, to date there have been few data from controlled studies on which to evaluate the efficacy and safety of attempting to stop labor and delay preterm delivery in patients after PROM.

Therefore, a prospective randomized study was developed to evaluate the use of tocolysis in patients with preterm labor after PROM. Because it has been shown that tocolytic therapy is generally less effective in patients with ruptured as opposed to intact membranes, we chose to study patients with PROM in the very premature gestation, in which any benefit from prolongation of pregnancy and the consequent improvement in neonatal outcome might be expected to be most likely demonstrated.

Material and methods

All patients admitted to the perinatal service of the Long Beach Memorial Women's Hospital either primarily or as a perinatal and/or maternal transport with PROM and singleton pregnancies between 25 weeks and 30 weeks, 6 days of gestation were requested to consent to randomization. Gestational age was determined by menstrual history and prenatal examinations or if these were questionable, by ultrasound measurements of biparietal diameter, abdominal circumference, and femur length. Patients with heart disease, diabetes mellitus, and thyrotoxicosis were excluded.

Ruptre of membranes was documented by speculum examination that confirmed the pooling of fluid in the

posterior vaginal fornix; alkaline pH by Nitrazine paper; ferning; and direct visualization of leakage of fluid from the cervical canal.

Cultures for group B *Streptococcus* and gonorrhea were obtained at this time. No digital examinations were performed unless the patient was thought to be in active labor; although some patients had been examined digitally before maternal transport. Patients with equivocal or undocumented rupture of membranes were not included in the study. Patients in advanced active labor, as defined by regular contractions and clear visibility of the fetal presenting parts on speculum examination, were also excluded. Patients were then evaluated for fetal distress by continuous electronic fetal heart rate monitoring and for clinical chorioamnionitis. The clinical diagnosis of chorioamnionitis required the presence of a temperature elevation of ≥100.4° F and any one of the following: maternal tachycardia (heart rate >100 bpm); fetal tachycardia (heart rate >160 bpm); maternal leukocytosis (white blood cells >15,000/mm³); uterine tenderness; or foul-smelling amniotic fluid. Patients with irreversible fetal distress or clinical chorioamnionitis were delivered immediately and were not randomized.

Consenting patients were randomized to receive either expectant management only or expectant management plus intravenous administration of ritodrine at the onset of contractions. Patients in the expectant management group were delivered for spontaneous labor, clinical chorioamnionitis, or fetal distress. Patients in the tocolytic group were similarly managed except at the onset of contractions with a frequency of three or more per 20 minutes; tocolytic therapy with intravenously administered ritodrine was begun. Patients were started on 150 μg/min, which was increased by 50 μg every 10 minutes until one of the following was achieved: decrease in contraction frequency to <one contraction/10 min; unacceptable complications or side effects; or when a maximum of 350 μg/min was reached. The infusion was continued for at least 12 hours after contractions abated. The maximum dosage was allowed for no more than 24 hours in the event that contractions were continuing at this drug level. Patients whose labors were successfully stopped were switched to oral ritodrine at an initial dosage of 10 mg every 3 hours, but the dosage was adjusted frequently to that needed to keep contractions at a minimum while still keeping the maternal pulse under 110 bpm. The patient was treated a second time with intravenous ritodrine as necessary. Patients with labor but with clinical infection or fetal distress were not given ritodrine. Additionally, patients reaching the end of week 31 were no longer eligible for tocolysis. Those who had been started on intravenous or oral administration of ritodrine and were still receiving either were discontinued at that point. After 31 weeks of gestation, patients were managed expectantly only as in the first group. No corticosteroids were used in either group; patients who had received corticosteroids before transfer were excluded from randomization.

140-150 bpm	18	22	
>150 bpm	8	9	NS

ROM = Rupture of membranes; GBS = group B *Streptococcus;* FHR = fetal heart rate; NS = not significant.

Whenever possible, ultrasound-directed amniocentesis was performed for Gram stain and culture of amniotic fluid as soon as possible after admission. Patients with successful amniocentesis and Gram stain positive for bacteria were excluded from the study. However, patients did not require amniocentesis to be eligible. In general, patients not in labor were kept on continuous fetal heart rate monitoring for at least 24 hours and if stable were then transferred to the antepartum unit and kept in the hospital until delivery. On the antepartum unit they were monitored with frequent temperature readings and daily prolonged (1 hour) nonstress tests. Patients with abnormal or concerning nonstress tests were transferred back to labor and delivery for continuous fetal heart rate monitoring.

The route of delivery for both groups was determined by means of the same criteria. All breech presentations were delivered by cesarean section. When induction of labor was necessary or spontaneous labor

occurred, cesarean section was performed for the usual obstetric indications. The presence of chorioamnionitis did not significantly alter indications for cesarean section or the duration of labor allowed. Prophylactic antibiotics were used on all patients delivered by cesarean section after cord clamping but in no patient who was delivered vaginally.

All maternal patient data were coded prospectively. Neonatal data were coded after neonatal discharge. The diagnosis of respiratory distress syndrome (RDS) was made only when clinical signs and chest x-ray films were confirmatory and the newborn infant required at least 24 hours of oxygen therapy.

Analysis of data was performed by means of χ^2 and two-tailed *t* tests.

Results

The study was conducted between January 1983 and September 1986. Seventy-nine patients were randomized; 39 to the tocolysis group and 40 to the expectant management group. Comparison of the prerandomization characteristics of both groups (Table I) would suggest that the two groups were well matched. In addition, there was no significant difference in the number of patients undergoing amniocentesis (nine of 39 in the tocolysis group vs 3 of 40 in the expectant group, $\chi^2 = 2.6$; not significant) or in the sex of the babies delivered (20 males/19 females in the tocolytic group vs 20 males/20 females in the expectant group) between the two groups.

Of the 39 patients randomized to receive tocolysis, 23 actually did receive ritodrine when contractions began. Of the 16 randomized to receive the drug but who did not, seven were ineligible because of clinical chorioamnionitis, five had gone beyond 31 weeks of gestation at the onset of labor, three had advanced cervical dilation at the time the drug was to be started, and one was infected and the fetus had no heart activity (stillborn).

The interval between the rupture of membranes and delivery in the two groups is compared in Table II. In addition, the subgroup of patients who actually received tocolytic therapy is separated for comparison. Both mean and intervallic data fail to show any prolongation of pregnancy with the addition of ritodrine to the more standard expectant management at the onset of labor. In addition, eight of 40 (20%) in the tocolytic group vs six of 40 (15%) in the expectant group (difference, not significant) reached 32 weeks of gestation, which in essence was the goal or point beyond which management in the two groups became similar. The causes and/or indications for delivery in both groups are listed in Table III.

Of the 23 patients who did receive ritodrine, 10 were delivered in <24 hours from the onset of therapy, six between 24 and 48 hours, one between 2 and 3 days, and six were delivered after the third day from the initiation of tocolytic therapy (4, 5, 6, 8, 11, and 23 days). There were no serious complications directly attributable to the ritodrine therapy in these patients, although one patient declined to be treated again after one full course when labor recurred because of side effects experienced with the first course.

Evaluation of maternal outcome in both groups does not reveal any striking dissimilarities. The cesarean section rate was similar between the two groups (18 of 39 [46%] in the tocolytic group vs 12 of 40 [30%] in the expectant group, $\chi^2 = 1.55$; not significant). The cesarean section rate was also similar in those patients who actually received ritodrine (eight of 23 [35%]). The incidence of chorioamnionitis was 14 of 39 (35%) in the tocolytic group vs seven of 40 (18%) in the expectant group; this difference was not statistically significantly different ($\chi^2 = 2.54$, $p = 0.12$). The incidence of cho-

>60	10 (30%)	12 (31%)	NS
Range	2-134	2-210	

RDS = Respiratory distress syndrome; IVH = intraventricular hemorrhage.
*Includes only babies discharged home alive (tocolytic group = 33, expectant group = 38).
†$t = 1.89$, $p = 0.08$.

rioamnionitis in those patients who actually received tocolysis was eight of 23 (30%). The occurrence of postpartum endomyometritis was also similar, with 10 of 39 (26%) in the tocolytic group and six of 40 (15%) in the expectant group but three of 23 (13%) in patients who received ritodrine. The incidence of prolonged postpartum stay (>3 days in vaginally delivered and >6 days for patients who had cesarean sections) was virtually identical between the two (three of 39 [8%] in the tocolytic group vs three of 40 [8%] in the expectant group).

Comparisons of neonatal outcome are found in Table IV. It can be seen that the birth weights, gestational ages at delivery, low frequencies of 5-minute Apgar scores, and incidences of significant neonatal complications are quite similar between the two groups. Although the mean hospital stays are numerically dissimilar between the two groups, this is not a normal curve, and the incidences of prolonged stays (>30 and >60 days) are quite similar. There were eight perinatal deaths among the 79 total patients in the study (101 of 1000). Two occurred in the expectant group (5%), including one stillbirth. There were six deaths in the tocolytic group (15%), also with one stillbirth. However, only two deaths (9%), both neonatal, occurred in the group that actually received tocolysis. The causes of death are listed in Table V.

Table V. Causes of perinatal deaths

Tocolytic group (6)

*Possible sepsis (1); possible pulmonary hypoplasia (1).

Comment

Because prematurity is the leading cause of perinatal mortality in patients with PROM, and since recent studies[3, 4] have suggested increased maternal safety in those patients not delivered immediately after PROM, most authors[1] have recently recommended various management schemes that are chiefly aimed at prolonging pregnancy. The addition of tocolytic therapy to help achieve these goals in such patients is an obvious alternative.

In the past, tocolytic agents were said to be contraindicated in patients with PROM[2] because of presumed lack of efficacy and concern about aggravating infectious morbidity. Although there are indeed theoretical reasons to believe that both of these concerns may be valid, there have been few investigative data on which to corroborate or refute them.

Most of the current information refers to the relative effectiveness of tocolytic agents in patients with PROM compared with patients with premature labor with intact membranes. Caritis et al.[5] used terbutaline and were able to gain a week or more in only 14% of patients with ruptured membranes as opposed to 59% of patients with unruptured membranes. Elliott[6] evaluated magnesium sulfate as a tocolytic agent and showed that 78% of patients with intact membranes were still undelivered after 48 hours as opposed to only 5% whose membranes were ruptured. In a collaborative study Curet et al.[7] were able to show a reduction of over 50% in the rate of RDS in patients with premature labor who are given ritodrine, but in patients with PROM similarly treated there was no difference between treated patients and controls in the incidence of RDS. Christensen et al.[8] have published a small randomized

clinical trial in patients in preterm labor with PROM, comparing ritodrine therapy with placebo. The only difference shown was a prolongation of pregnancy beyond 24 hours in the tocolytic group, but beyond 48 hours no difference was shown. There was no improvement seen in outcome for any newborn. However, there was no apparent increase in the rate of infectious complications in either mothers or neonates.

In designing this randomized clinical study, the question that we asked was whether the planned addition of a tocolytic agent at the onset of labor was of any benefit in terms of prolonging pregnancy and/or improving neonatal outcome as compared with expectant management alone. Because it is probably true that tocolysis with PROM cannot be expected to be as effective as with preterm labor with intact membranes, we chose to study only those patients with very early gestational ages for whom any prolongation of pregnancy would be expected to result in the greatest benefit to the newborn. Goldenberg et al.[9] have suggested that between the gestational ages of 25 and 30 weeks, improvements in survival of 0.9% to 3% per day and 6% to 21% per week could be expected.

The results of this clinical trial do not suggest that there is any benefit to adding tocolysis to expectant management either in terms of prolonging the interval between PROM and delivery or in reducing morbidity from prematurity or perinatal mortality. As seen in Table II, there is a striking similarity in the time intervals between PROM and delivery for the two groups both in terms of mean days gained and in the intervallic data. In terms of the overall goal, that is, to reach 32 weeks of gestation, since that was the time when management became similar in the two groups, no difference was seen.

With respect to neonatal outcome, virtually all parameters evaluated were similar between the two groups. This is true for birth weights and gestational ages at delivery and for morbidity of prematurity and the duration of neonatal hospital stay. It would be expected that any neonatal benefit from prolonging pregnancy with tocolysis in these patients would be shown in these outcome parameters, and none were seen.

It is tempting to try to compare the 23 patients who actually received ritodrine with a similar group of patients from the expectant management group. However, one cannot validly extract from the expectant group which patients should be compared and at what point in time the onset of labor for these patients should be defined, since no attempt was made prospectively to identify them. Valid comparisons should not be made between this group that actually received tocolysis and the overall expectant group, since the latter includes patients who went beyond 32 weeks of gestation, infected patients, and those who were in advanced labor when their labors were first discovered. Therefore one cannot conclude from this study that tocolysis in laboring patients with PROM shows no apparent benefit over no tocolysis, as was suggested in the study by Christensen et al.[8] Rather, what was shown was that the addition of planned tocolysis to expectant management did not demonstrate any apparent benefit over expectant management alone.

One additional point that this study illustrates is not only lack of apparent efficacy but limited applicability, since only 23 of 39 (59%) patients randomized to receive ritodrine actually did so. Most frequently this was because of infection or advanced labor at the time that diagnosis of labor was made. The impact of this consideration is important, since even if limited efficacy could be shown with tocolysis in patients with PROM in larger studies, the fact would remain that the overall impact would be limited by lack of complete applicability. This problem has also been identified in premature labor in general.[2]

Although this study does not demonstrate any apparent benefit from tocolysis, it does not suggest any deleterious effect from such treatment in patients with PROM. There was no increase in the incidence of any infectious complication. Though there is a numerical trend toward more chorioamnionitis in the tocolytic group, this trend was not limited to those patients who actually received tocolysis, for whom the incidence was actually less (seven of 23 [30%]) than in the overall tocolytic group (14 of 39 [35%]). However, it is possible that a larger study might demonstrate such deleterious effects. Additionally, there were no other apparent harmful maternal or neonatal effects.

Perhaps the reason that no benefit was shown with the addition of tocolytic therapy in this study is that once labor has been estabished in patients with PROM it is already too late. Perhaps earlier detection of contractions and earlier institution of therapy might improve efficacy. One choice might be frequent contraction monitoring with a device such as that described by Katz et al.,[10] the "ambulatory tokodynamometer." Alternatively or additionally, prophylactic oral agents might be of benefit as shown by Levy and Warsof,[11] who showed in a prospective randomized study that oral ritodrine given to patients not in labor with PROM substantially prolonged pregnancy over control patients; however, although babies were slightly larger in the treatment group, no other improvement in neonatal outcome was shown.

Although current studies may show that short-term gains such as 24 or 48 hours may be accomplished with intravenous therapy once labor is started, there is a question of whether there are any benefits to be derived

from such short delays. The benefit of corticosteroids given to the mother to reduce neonatal RDS is at best questionable in patients with PROM and may increase the risk of infection.[1] Delaying delivery 24 to 48 hours alone in the presence of PROM has been suggested to lower the chances of RDS, but again these effects are controversial.[12]

In conclusion, although this study is limited by relatively small numbers, it was conducted in those gestational ages during which prolongation of pregnancy might have been expected to produce the greatest benefit in neonatal outcome. Nevertheless, no benefit could be demonstrated with the addition of a proved effective tocolytic agent after the onset of labor over expectant management alone in the patient with PROM in the very premature gestational period. Some form of expectant management with careful attention to avoiding complications from infection and asphyxia remains the management of choice for providing the best outcome in patients with PROM. It appears that tocolysis at the onset of labor will do little to improve on this form of management although further studies certainly should be done to confirm or refute this conclusion.

Detection of *Chlamydia trachomatis* cervical infection: A comparison of Papanicolaou and immunofluorescent staining with cell culture

Thomas C. Quinn, M.D., Prabodh K. Gupta, M.D., Ronald T. Burkman, M.D., Elizabeth W. Kappus, B.S., Marguerite Barbacci, B.S.N., M.P.H., and Michael R. Spence, M.D., M.P.H.

Bethesda, Maryland

We compared tissue culture with Papanicolaou-stained cervical smears, endocervical cytologic smears stained with immunofluorescent monoclonal antibody, and a direct immunofluorescent stain of cervical specimens (MicroTrak) for detection of *Chlamydia trachomatis* in cervical specimens. Fifty-one (21%) of 245 women had positive cultures for *C. trachomatis*, 14 (27%) of whom had clinical evidence of cervicitis. With the criteria of intracytoplasmic coccoid inclusion bodies within metaplastic cells, 45 (34%) of 130 Papanicolaou smears were read as suggestive for *C. trachomatis*. Seventeen of the 45 positive Papanicolaou smears were positive on culture and 28 were negative (sensitivity 54%, specificity 71%). In contrast, 48 of 51 women with positive cultures and one woman with a negative culture had positive immunofluorescent-stained cytologic smears (sensitivity 94%, specificity 99%, with positive predictive value of 98%). Similarly, 47 of 51 women with positive cultures also had positive results with MicroTrak direct immunofluorescent stain, with only one positive specimen in 196 women with negative cultures (sensitivity 92%, specificity 99%, with positive predictive value of 98%). This study demonstrates that immunofluorescent staining of cervical specimens or of cytologic smears is a more sensitive and specific method than routine Papanicolaou smear for detection of chlamydia infection in a high-prevalence population. (Am J Obstet Gynecol 1987;157:394-9.)

Key words: *Chlamydia trachomatis*, Papanicolaou smear, cervicitis, immunofluorescent staining

Chlamydia trachomatis is presently the most frequent sexually transmitted bacterial pathogen in the United States. It is associated with a wide variety of genital and ocular infections including mucopurulent cervicitis, endometritis, salpingitis, urethritis, epididymitis, proctitis, neonatal and adult inclusion conjunctivitis, trachoma, and pneumonia of newborn infants and immunosuppressed adults.[1] Despite the wide variety of clinical syndromes and associated morbidity, screening for chlamydia infections is still not widely performed by physicians in the United States. The standard method for screening for chlamydia is in vitro tissue culture of specimens. Cultures, however, are not widely available, are costly, demand strict transport requirements, and take approximately 5 days before results are made available to the physician. More recently, several new diagnostic assays for chlamydia were licensed in the United States. These include a direct immunofluorescent monoclonal antibody stain and enzyme-linked immunoabsorbent assays that detect chlamydial antigen in the cervical and urethral secretions. Previous studies have demonstrated that these assays are rapid, inexpensive, and relatively sensitive and specific compared with culture.[2-4]

An alternative method of detection of chlamydial infection has been by cytologic identification on routine Papanicolaou smears. Gupta et al.[5] suggested that chlamydia could be diagnosed on routine Papanicolaou smears by the identification of intracytoplasmic coccoid inclusion bodies in enlarged metaplastic cells. More recently, Shafer et al.[6, 7] demonstrated that increased numbers of histiocytes, polymorphonuclear leukocytes, and transformed lymphocytes were significantly associated with chlamydia infection. Using these criteria, Kiviat et al.[8] suggested a two-step method by which cytologic Papanicolaou smears suspicious for chlamydia could be used for the selection of patients for confirmatory testing.[9]

Although there has been controversy regarding the reliability of some of these criteria for the diagnosis of chlamydia,[7, 10] certainly a sensitive and specific test that includes use of routine cytologic smears for the detec-

tion of chlamydia would be advantageous for screening of women, since approximately 25 million women undergo cytologic screening annually in the United States. We therefore undertook a study to compare several of these diagnostic methods for the detection of cervical chlamydial infection.

Material and methods

Study population. Patients were prospectively enrolled from three clinics at The Johns Hopkins Hospital and the Baltimore City Sexually Transmitted Diseases (STD) Clinic. The study group consisted of 204 (85%) pregnant women admitted for an abortion procedure, 22 (9%) evaluated at the STD clinic, and 19 (6%) attending the obstetrics-gynecology clinic for routine examination. Patients who had received antibiotics in the month prior to enrollment were excluded from the study.

Patient examination. Information concerning demography, menstrual history, contraceptive methods, sexual history, and history of sexually transmitted diseases was obtained from all women. All patients underwent a physical and pelvic examination. Information regarding the type of vaginal discharge, the color of cervical secretions as viewed on a cotton-tipped swab,[11] the presence or absence of cervical friability and bleeding, the presence of cervical ectopy, and the presence of erythema or edema in the area of ectopy was recorded. Patients were diagnosed as having cervicitis if cervical friability, hypertrophic ectopy, and a mucopurulent cervical discharge were present.[12]

Collection of specimens. Specimens obtained from each patient included a cervical smear for cytologic examination (Papanicolaou smear), a cervical smear for immunofluorescent staining, an endocervical swab for isolation of *Neisseria gonorrhoeae*, and an endocervical swab for direct immunofluorescent staining (MicroTrak, Syva Corp., Palo Alto, California) and tissue culture isolation of *C. trachomatis*. Specimens for each test were collected according to computer-generated random order.

Cultures for *N. gonorrhoeae* were obtained by inserting a wooden shaft, cotton-tipped swab into the endocervical canal, rotating for 15 seconds, and immediately inoculating it onto Thayer-Martin media, followed by incubation and identification by standard methods.[13]

Specimens for isolation and detection of *C. trachomatis* by tissue culture assay and direct immunofluorescent staining were obtained with a Dacron polyester fiber–tipped plastic swab (American Scientific Products, McGaw Park, Illinois), which was then rolled onto a circular area 8 mm in diameter of a microscope slide (MicroTrak) and placed in 1.5 ml of 0.2 mmol/L sucrose-phosphate–buffered transport media. The slides were air-dried and fixed in 2 ml of water-free acetone. Culture samples and slides were transported to the laboratory and frozen at −70° C for 24 hours.

Laboratory procedures. Tissue culture isolation of *C. trachomatis* was carried out in 96-well microtiter plates on McCoy cell monolayers as previously described.[14] After incubation for 72 hours at 35° C, two wells were stained with 30 μl of fluorescein-conjugated monoclonal antibody (Syva Corp.). The remaining two wells were disrupted and passaged onto fresh McCoy cell monolayers for another 72 hours. Culture monolayers were examined for characteristic inclusions at ×100 magnification on a Zeiss fluorescence microscope. The presence of one inclusion was considered positive for *C. trachomatis*.

MicroTrak slides were stained with 30 μl of fluorescein-conjugated monoclonal antibody against *C. trachomatis* (Syva Corp.). After an incubation of 15 minutes at room temperature, the slides were rinsed in distilled water, air dried, and scanned at ×630 magnification on a Zeiss fluorescent microscope. Typical elementary bodies appear as well-defined, sharply edged disks of apple green fluorescence.[2] The presence of five or more elementary bodies was the criterion used for positive identification.

Endocervical scrapings for immunofluorescent detection of *C. trachomatis* were removed from fixative, rinsed in phosphate-buffered saline, and stained with 100 μl of fluorescein-conjugated monoclonal antibody to *C. trachomatis* (Syva Corp.). A coverslip was applied to each slide to ensure even coverage of the antibody and the slides were incubated for 30 minutes at room temperature in a humidified atmosphere. The slides were rinsed in distilled water, allowed to air dry, and covered with a 22 × 50 mm coverslip and mounting fluid. The entire slide was then scanned at ×630 magnification on a Zeiss fluorescent microscope. The presence of ≥10 elementary bodies per slide was the criterion used for positive identification of *C. trachomatis* on cytologic smears because of the larger surface area of the slide to be examined in contrast to the 8 mm diameter area of a MicroTrak slide.

Cytologic methods. A duplicate cervicovaginal smear was sent to the cytopathology laboratory and stained with a modified Papanicolaou stain. All cytologic slide evaluations were conducted by one person (P. K. G.) and a special form was used for each case. The presence or absence of endocervical cells, metaplastic cells, and blood was noted. The presence of each type of inflammatory cell (polymorphonuclear leukocytes, lymphocytes, plasma cells, and histiocytes) was quantified and the epithelial cytologic findings were described in detail. Assessment for *C. trachomatis* infection was first performed with previously published criteria,[5] including metaplastic cell morphologic features, the finding

‡Cervicitis was defined as the presence of all three criteria—cervical friability, cervical ectopy, and a mucopurulent cervical discharge.

of intracytoplasmic coccoid inclusion bodies in metaplastic cells, and multinucleation and intracytoplasmic vacuolation of these cells. Cytologic slides were then reanalyzed for chlamydia according to criteria recently described by Kiviat et al.[8] Chlamydia infection was suspected by these criteria if there were ≥30 histiocytes in at least three fields, if transformed lymphocytes were present, or if there were increased numbers of leukocytes and plasma cells.

MicroTrak smears, immunofluorescent cervical smears, and cervical Papanicolaou smears were read independently by three investigators that were blinded to the other laboratory results or clinical information.

Statistical analyses. Differences in proportions were tested for significance by χ^2 analysis and means were compared by use of Student's *t* test. Univariate and multiple logistic regression analyses were used to determine associations between clinical signs of infection, epithelial cell changes, and presence or absence of cervical pathogens.

Results

Isolation of *C. trachomatis* by tissue culture assay. Fifty-one (21%) of the 245 women enrolled in the study had positive cervical cultures for *C. trachomatis*. Women infected with chlamydia were significantly younger, with a mean age of 18.6 years, than chlamydia-negative women, who had a mean age of 22.4 years ($p < 0.0001$; Table I). There were no significant differences noted in racial or marital status, which were predominantly black (79%) and unmarried (92%), respectively (Table I).

Fourteen (27%) of the 51 chlamydia-positive women had cervicitis on examination compared with 22 (11%) of 194 women with negative cultures ($p < 0.007$; Table I). In univariate analysis of the clinical variables of cervicitis, the presence of a mucopurulent cervical discharge ($p < 0.002$), cervical ectopy ($p < 0.02$), and cervical friability ($p < 0.01$) was associated with chlamydial infection (Table I).

Evaluation of cytologic screening by Papanicolaou smears for *C. trachomatis* infection. The reliability of Papanicolaou smear diagnosis of chlamydial infections compared with in vitro culture was examined by means of standard cytologic criteria.[7] Of the 245 specimens obtained, 115 were classified as inadequate because of insufficient endocervical components (95 specimens), excessive inflammation with cellular obscuring (23), excessive cytolysis (4), and heavy fresh or old blood (15). Of the remaining 130 specimens, 45 (35%) were interpreted as positive for *C. trachomatis*. Of 28 women with positive cultures and evaluable cytologic smears, 15 had Papanicolaou smears interpreted as positive for *C. trachomatis* and 13 had smears interpreted as negative (Table II). Of the 102 women with negative cultures and evaluable cytologic smears, 30 had Papanicolaou smears interpreted as positive and 72 had smears interpreted as negative (Table II). Thus, in this relatively high-prevalence population for *C. trachomatis* infection, an evaluable cytologic Papanicolaou smear had a sen-

*Only 130 slides were evaluable by standard cytologic criteria for *C. trachomatis* screening.

†The modified cytologic criteria incorporate the finding of inflammatory cells for detection of *C. trachomatis*. A total of 245 slides were evaluable by this method.

sitivity of 54%, a specificity of 71%, a positive predictive value of 33%, and a negative predictive value of 85% when compared with culture.

In a reanalysis of cytologic diagnosis for *C. trachomatis*, all Papanicolaou smears were screened according to criteria described by Kiviat et al.[8] Slides with increased histiocytes, leukocytes, plasma cells, and/or transformed lymphocytes were interpreted as positive for *C. trachomatis*. Of 51 women with positive cultures, 16 had Papanicolaou smears interpreted as positive for chlamydia. Of the 194 women with negative cultures, 164 had negative Papanicolaou smears for chlamydia. Thus, with these modified criteria of Kiviat et al.,[8] the Papanicolaou smear had a sensitivity of 31%, a specificity of 84%, a positive predictive value of 35%, and a negative predictive value of 82%.

Univariate analysis of Papanicolaou smear findings and detection of *C. trachomatis* by culture showed that only the presence of polymorphonuclear leukocytes significantly correlated with a positive chlamydia culture (Table III). The presence of metaplastic cells, histiocytes, plasma cells, or lymphocytes did not correlate significantly with culture results. In addition, the presence of *Trichomonas vaginalis* in Papanicolaou smears of 12 (43%) of 28 patients with positive cultures versus 17 (17%) of 102 patients with negative cultures ($p < 0.007$) correlated with positive culture results for *C. trachomatis*.

Evaluation of direct immunofluorescence, staining of cytologic smears, and cervical specimens (MicroTrak). Cytologic smears were analyzed for *C. trachomatis* infection after staining with fluorescein-conjugated monoclonal antibody against *C. trachomatis*. All 245 duplicate cytologic smears were evaluated, and

Table III. Correlation of cytologic findings on Papanicolaou smears with *C. trachomatis* culture results

Lymphocytes (>0)	0.96	0.33
Polymorphonuclear leukocytes (≥3+)	5.07	0.02

no slides were interpreted as inadequate. Forty-eight (94%) of 51 patients with positive cultures had positive immunofluorescent-cytologic smears and 193 (99%) of 194 women with negative cultures had negative smears (Table IV). The sensitivity and specificity of immunofluorescent-cytologic smears were 94% and 99%, respectively. The positive and negative predictive values were each 98%.

Staining with monoclonal antibody occasionally identified chlamydia inclusions on cytologic smears. Of the 48 Papanicolaou smears that were read as positive for chlamydia only nine had inclusions present on immunofluorescent-stained cytologic smears. Thus 36 culture-negative and immunofluorescent-negative smears were falsely interpreted as showing chlamydia inclusions on Papanicolaou-stained smears.

MicroTrak direct immunofluorescent staining of endocervical smears was also compared with chlamydia cultures. Forty-seven (92%) of 51 women with positive cultures had positive smears and 193 of 194 women

Table IV. Comparison of direct immunofluorescent staining of cytologic smears and endocervical specimens by MicroTrak

Staining	C. trachomatis *culture result*		*Total*
	Positive	*Negative*	
Immunofluorescent stain of cytologic smears			
Positive (n)	48	1	49
Negative (n)	3	193	196
Sensitivity (%)			94
Specificity (%)			99
Positive predictive value (%)			98
Negative predictive value (%)			98
Immunofluorescent stain of cervical specimens (MicroTrak)			
Positive (n)	47	1	48
Negative (n)	4	193	197
Sensitivity (%)			92
Specificity (%)			99
Positive predictive value (%)			98
Negative predictive value (%)			98

with negative cultures had negative smears (Table IV). Thus, in this population, the MicroTrak direct immunofluorescent smear had a sensitivity and a specificity of 92% and 99%, with positive and negative predictive values of 98% and 98%, respectively.

Comment

This study compared four different methods currently recommended for screening of *C. trachomatis* infection in women: culture, Papanicolaou smear, direct immunofluorescent staining of cytologic smears, and direct immunofluorescent staining of a cervical smear (MicroTrak). Detection of chlamydia has become increasingly important because of its high prevalence in our population (5 to 10 million infected people), its high frequency of asymptomatic infections, and its associated morbidity. Chlamydial infections during pregnancy are a significant problem since they have been associated with prematurity, increased fetal wastage, postpartum and postabortal endometritis, and neonatal infections, such as conjunctivitis, pneumonia, and possibly otitis media.[11] However, screening of *C. trachomatis* in pregnant women is rarely performed. We therefore undertook this comparative study of diagnostic assays predominantly in women who were in the first trimester of pregnancy and some nonpregnant women from other clinics.

The population sampled had a relatively high infection rate of 21%, not uncommon for young, sexually active, inner-city black women.[5] Although young age and evidence of cervicitis correlated with chlamydia infection (Table I), the majority of chlamydia-infected women were asymptomatic. While the presence of a mucopurulent cervical discharge in a young, sexually active woman was highly suggestive of chlamydia infection,[12] its absence did not rule out the diagnosis.

The use of the Papanicolaou smear has been recommended for use in chlamydia screening for the last decade, but the reliability of this test for the detection of chlamydia has been controversial. Naib[15] originally described chlamydia-induced changes noted in Papanicolaou-stained smears of newborn infants with neonatal conjunctivitis and from their mothers. Gupta et al.[5] further described the cytologic findings of chlamydia cervicitis. Multinucleated, metaplastic cells with intracytoplasmic vacuoles or coccobacillary bodies on Papanicolaou smears became the standard criteria for diagnosis of chlamydia cervical infection. However, several subsequent studies demonstrated that this method was relatively insensitive for the detection of chlamydia.[7, 10, 16]

In this study, nearly half of the Papanicolaou smears could not be evaluated because of relatively strict criteria. For those that could be evaluated, the Papanicolaou smear had a sensitivity of 54%, a specificity of 71%, and positive and negative predictive values of 33% and 85%, respectively. Although chlamydia inclusions were suspected in 45 specimens, only 15 were culture positive, of which only nine had inclusions demonstrable by immunofluorescent staining. Thus cytologic diagnosis of chlamydia infection on Papanicolaou smear in predominantly pregnant women was insensitive.

More recently, several studies have demonstrated that nonspecific inflammatory cellular atypias were significantly associated with *C. trachomatis* infection.[6-8] In a study of 148 sexually active adolescents, Shafer et al.[7] found that 23 (15.5%) were infected with *C. trachomatis*. In multiple logistic regression analysis only inflammatory changes and lymphocytes correlated with chlamydia infection. In a subsequent study of 265 women with an incidence of 29%, Kiviat et al.[8] found that chlamydia infection was associated with the presence of

metaplastic cells, transformed lymphocytes, and increased histiocytes. These criteria for the detection of chlamydia had a sensitivity of 95%, a specificity of 75%, and a positive predictive value of 50%. Because of the high sensitivity of these criteria they suggested a two-step approach by which patients with a first Papanicolaou smear that was suspicious for *C. trachomatis* infection would have a second cytologic smear stained with monoclonal antibody to *C. trachomatis*. This two-step approach resulted in a sensitivity of 76%, a specificity of 100%, and a positive predictive value of 100%.[9]

By adopting the cytologic criteria of Kiviat et al.,[8] we found a relatively low sensitivity rate of 31%, a specificity rate of 84%, a positive predictive value of 35%, and a negative predictive value of 82% for Papanicolaou smear diagnosis. By univariate and multivariate logistic regression, we found that only the presence of increased polymorphonuclear leukocytes correlated with chlamydia isolation. Differences in patient populations may partially explain these differences since Kiviat et al.[8] excluded pregnant women and had a greater number of women with cervicitis. It may be that ectopy of pregnancy may alter the cytologic diagnosis of chlamydia, and further studies are warranted in nonpregnant women.

Our data support the finding that immunofluorescent staining of cytologic smears or of cervical specimens (MicroTrak) is highly effective in screening for *C. trachomatis*. Both tests have very high sensitivities and specificities when compared with culture (Table IV). Indeed in one case immunofluorescent staining may have detected a true positive specimen that was negative by culture. Positive and negative predictive values in high-prevalence populations have been 98% for both tests, but subsequent studies will have to determine what these values are for low-prevalence populations where the level of detectable antigen may be lower.

Routine immunofluorescent staining of cytologic smears should not be recommended, however, since the reading of these smears is much more labor intensive than immunofluorescent staining of cervical smears as in the MicroTrak assay. In this latter test, microscopic examination is limited to an area of the slide 8 mm in diameter, whereas in cytologic smears a greater area of the slide must be examined. Deficiencies ascribed to these tests include the dependency on technician proficiency in discriminating elementary bodies of chlamydia from artifacts and the potential for detecting antigen in successfully treated patients. Further studies are warranted for the evaluation of these tests in different patient populations.

In summary, our data suggest that routine screening of all high-risk individuals for chlamydia infection should be performed, particularly since the majority of our infected patients were asymptomatic, and that immunofluorescent staining of cervical smears (MicroTrak) and immunofluorescent staining of cytologic smears are sensitive and specific assays for the detection of *C. trachomatis*.

We thank Dr. Barbara Judson for providing monoclonal antibody and for computer analysis of data. We thank Rhonda Reese for preparation of the manuscript.

Genetic heterogeneity of prematurity and intrauterine growth retardation: Clues from the Old Order Amish

Muin J. Khoury, M.D., Ph.D., and Bernice H. Cohen, Ph.D., M.P.H.
Baltimore, Maryland

We studied differences in the role of genetic factors in prematurity and intrauterine growth retardation with the use of data on 312 Amish singleton live children ascertained from Amish records in Lancaster county, Pennsylvania, between 1969 and 1980. Birth and death certificates were obtained on all children, and inbreeding coefficients of child, mother, and father were computed by use of the path method of tracing common ancestors in a unique genealogic registry of Amish ancestors dating back to the 1700s. Multivariate analysis with linear and log linear models showed that a lower mean gestational age and a higher risk of prematurity (<37 weeks) and borderline maturity (37 to 38 weeks) were significantly associated with increased maternal inbreeding but not child or paternal inbreeding. On the other hand, a higher risk of intrauterine growth retardation (less than the tenth percentile in birth weight for gestational age) and mild intrauterine growth delay (tenth to twenty-fifth percentile) were associated with increased child inbreeding but not maternal or paternal inbreeding. The analysis suggests the presence of genetic heterogeneity in the etiology of prematurity and intrauterine growth retardation; while prematurity is mostly related to the maternal genotype, intrauterine growth retardation is related to the fetal genotype. The study reemphasizes the need for separating low birth weight into prematurity and intrauterine growth retardation in genetic and epidemiologic studies. (Am J Obstet Gynecol 1987;157:400-10.)

Key words: Genetics, inbreeding, intrauterine growth retardation, Old Order Amish, prematurity

Low birth weight (<2500 gm) has long been recognized as an important predictor of infant mortality and childhood morbidity[1] and has been the focus of many epidemiologic studies[2] that have attempted to characterize its risk profiles in order to devise prevention strategies.[3] However, studies of the causes of low birth weight have infrequently examined the two components of low birth weight: prematurity (gestational age <37 weeks) and intrauterine growth retardation (IUGR, low birth weight for gestational age). Although the two entities have different morbidity and mortality patterns as well as different pathophysiologic and epidemiologic characteristics,[4, 5] only recently have observational and intervention studies begun to measure differences in risk factor associations between prematurity and IUGR.[5] Among these risk profiles, however, differences in genetic factors have rarely been explored. Although birth weight is known to be correlated among siblings,[6] only a few studies have examined whether such relationships are due to correlations in length of gestation or intrauterine growth or both.[7] This may be partly due to the lack of uniform definition of IUGR[8] as well as to the high degree of correlation between IUGR and prematurity.[9]

In this study, we use data from a unique population, the Old Order Amish, to describe the differential impact of child and parental inbreeding on the length of gestation and intrauterine growth. Our analysis suggests the existence of autosomal recessive genes affecting prematurity and IUGR. Moreover, the study suggests that, while prematurity is associated primarily with the maternal genotype, IUGR is associated with the fetal genotype.

Methods

The study population. The Old Order Amish is a religious isolate that has attracted the interest of researchers in many fields including sociology, genetics, epidemiology, and demography.[10] This interest stems from the unique characteristics of the Amish that facilitate inferences concerning the role of genetic factors in disease. Such characteristics include their reproductive isolation, close inbreeding, farming way of life, homogeneous sociocultural patterns, high standards of living, and large family size.[10] In addition, the Amish have kept extensive family and genealogic records dating back to the time of pioneer migrants in the 1700s.[11]

This study is part of a case-control investigation of the impact of inbreeding on prereproductive mortality

in the Old Order Amish of Lancaster County, Pennsylvania.[12] Cases included all offspring who died at less than 20 years of age between 1969 and 1980 in the Lancaster County community. These were ascertained via multiple sources[10] including: (1) the Diary, which is an Amish monthly publication that publishes lists of births, deaths, and marriages among the Old Order Amish; (2) a 1980 Amish population directory, which is a complete population and family census of Lancaster County Amish; (3) death certificates obtained from the Pennsylvania State Health Department. On the other hand, controls included live children randomly selected from an annual listing of births published in the Diary as well as children listed in the 1980 directory. Controls were frequency matched to cases by year of birth and were alive as of December 31, 1980. In this analysis, only live-born singleton cases and controls were used and three groups were created: (1) Group 1 consisted of children who were still alive as of December 31, 1980 (live children). (2) Group 2 consisted of children who died during childhood (deaths between age 1 and 20 years, child deaths). As shown previously,[10] more than two thirds of these deaths were due to accidents. (3) Group 3 consisted of offspring who died before reaching age 1 year (infant deaths). As shown previously, the most common cause of death in this group was prematurity followed by congenital malformations.[10] For all children, information was abstracted from birth certificates obtained from the Pennsylvania State Health Department on birth variables including last menstrual period, parental ages, maternal parity, birth weight, gestational age, prenatal or delivery complications, and recorded congenital malformations. Information was abstracted from death records on causes of death.

Methods of analysis

Outcome variables. The length of gestation was computed by use of information on last menstrual period and birth date (number of completed weeks past last menstrual period). For about 13% of birth certificates, gestational age information could not be derived, and these children had to be excluded from the analysis. The length of gestation was analyzed as a continuous variable (mean gestational age in weeks) and also categorized into (1) preterm delivery ($\leq$36 weeks), (2) borderline maturity (37 to 38 weeks), and (3) term ($\geq$38 weeks). No instances of postterm delivery (>42 weeks) were recorded. Intrauterine growth was analyzed with birth weight used as a continuous variable as obtained on birth certificates (<2% of certificates had a missing birth weight). However, as birth weight is highly associated with gestational age, the distribution of birth weight by gestational age was used. Intrauterine growth was categorized into (1) IUGR, defined as a birth weight less than the tenth percentile for gestational age on the basis of sex- and gestational age–specific birth weight distribution of the total singleton births in the U.S. white population[13]; (2) mild growth delay (if birth weight for gestational age was between the tenth and twenty-fifth percentiles); (3) no growth delay (greater than the twenty-fifth percentile). In order to compute the intrauterine growth variable, information on gestational age had to be known. In the final analysis, only certificates with reported birth weight and gestational age were included (group 1, 183/208; group 2, 69/93; and group 3, 60/65).

Computation of inbreeding coefficients. The inbreeding coefficient of an individual represents the probability that the individual carries at an autosomal genetic locus two alleles that are identical by descent.[11] Inbreeding increases the frequency of recessive genotypes in the individual, which may be unrecognized in the heterozygous state but become deleterious in the homozygous state. Significant inbreeding effects on the incidence of a trait or disease indicate the presence of one or more autosomal recessive genes affecting the condition.[11] In this study, the inbreeding coefficients (F) of child, mother, and father were calculated by linking individuals with the computerized Amish genealogic registry[10] by means of unique family genealogic numbers. The registry is a complete ancestral history of present-day Amish of Lancaster County. It contains information on 8163 family entries with 42,465 offspring spanning more than 200 years and dating back to the pioneer migrants in the 1700s.[11] Inbreeding coefficients were calculated by use of the path method of identifying common ancestors as described elsewhere.[10]

Analysis of inbreeding effects. The effects of the inbreeding coefficients F of child, mother, and father on the length of gestation and the rate of intrauterine growth were studied. Analyses were conducted within each of the three groups. Inbreeding coefficients were used as continuous variables as well as categorized into four levels of increasing inbreeding: (1) $F < 1/256$ (farther than level of third cousins), (2) $1/128 > F \geq 1/256$ (corresponding to inbreeding between third cousin and second cousin once removed), (3) $1/64 > F \geq 1/128$ (corresponding to inbreeding between second cousin once removed and second cousin), and (4) $F \geq 1/64$ (corresponding to inbreeding closer than second cousin). Because first-cousin marriages are prohibited by religion, no direct first-cousin marriages are seen in this study population. It is to be noted that no child had an inbreeding coefficient equal to 0, which indicates the extent of close inbreeding in the Amish. Also only one mother's and three fathers' coefficients were equal to 0.

Univariate analyses included evaluation of the separate effects of child's, mother's, and father's F on mean gestational age and birth weight with the use of analysis

*$p < 0.05$ (simple linear regression of gestational age on mother F).
†$p < 0.05$, χ^2 for trend (both groups combined).

of variance (to compare the four inbreeding levels) and simple linear regression (when F is used as a continuous measure). The incidences of prematurity and IUGR were compared between the four levels of inbreeding and χ^2 for trend was used to test for statistical significance of trends. However, because the levels of inbreeding of child, mother, and father may be correlated and other prenatal and birth-related factors may act as confounders, we used multivariate analysis to study the independent effects of child's, mother's, and father's F on mean gestational age (multiple linear regression) and the incidences of IUGR and prematurity (multiple logistic regression). Other factors considered in the multivariate analyses included sex, maternal and paternal ages, year of birth, birth order, sibship size, history of previous siblings who died in infancy, and father's occupation (farmer versus nonfarmer).

Finally, because prematurity and IUGR tend to be correlated, we used the log linear model,[15] which can incorporate both outcomes in the analysis and can examine the relationship of inbreeding among child, mother, and father with each of these outcomes after they are adjusted for one another and the relationship between the two outcomes. The log linear model is a useful technique to analyze the relationship among cross-classified data and is described in detail by Fienberg.[15] Essentially, the model fits a linear combination of parameters to derive an expected number of individuals in each cell. Parameters are estimated by use of the maximum likelihood procedure and can be interpreted in terms of odds ratios (similar to logistic regression). However, one main advantage over logistic regression is the ability to derive independent relationships among all variables in the model, including one or more dependent variables. Its disadvantage over the usual logistic model is that all variables have to be categorical.

Results

Characteristics of the three groups in the study. Table I shows birth weight and gestational age characteristics and inbreeding patterns of children in the three study groups. Generally, infant deaths (group 3) had a lower mean birth weight and gestational age and an increased frequency of IUGR when compared with children in the other two groups. However, few

children were born before 37 weeks (only three in group 1 and four in group 2). Likewise, very few children had IUGR (<tenth percentile) (only one in group 1 and one in group 2). Therefore our ability to detect statistical significance in these outcomes is limited by the small number of affected children. With respect to inbreeding characteristics, group 3 has a higher mean child inbreeding coefficient than group 1, which is consistent with earlier findings that inbreeding is a risk factor for infant mortality. The higher child F in group 2 than in group 1 is not statistically significant. Also both mean mother F and mean father F do not show significant differences among the three groups.

Unadjusted inbreeding effects on the length of gestation

Child inbreeding. Table II shows the unadjusted effects of child inbreeding levels on mean gestational age and the incidence of premature birth. In both groups 1 and 2, it can be seen that with increasing child inbreeding levels, there is a progressive decline in mean gestational age (a difference of almost 1 week between the two extremes) and an increase in the frequency of children born at <37 weeks' gestation and at 37 to 38 weeks' gestation (combined). However, trends in both groups were of borderline statistical significance ($0.05 < p < 0.10$). However, in group 3 (infant deaths), inbreeding is not associated with a reduction of mean gestational age. On the contrary, there is a suggestion of an opposite trend.

Maternal inbreeding. Table III shows the unadjusted effects of mother inbreeding levels on mean gestational age and the incidence of premature birth. Again, one notes in group 1 that with increasing maternal inbreeding levels, there is a progressive decline in mean gestational age and an increase in the frequency of children born at <37 weeks' gestation and at 37 to 38 weeks' gestation (combined). Findings in group 2 are generally consistent with those from group 1 and are statistically significant in the analysis of mean gestational age. However, in group 3 (infant deaths), inbreeding is not associated with a reduction of mean gestational age, again with a suggestion of an opposite trend (not significant).

Paternal inbreeding. Table IV shows the unadjusted effects of paternal inbreeding levels on mean gestational age and the incidence of premature birth. In all three groups, no significant effects of father's inbreeding coefficients can be seen.

Unadjusted inbreeding effects on intrauterine growth

Child inbreeding. Table V shows the unadjusted effects of child inbreeding levels on mean birth weight and the incidence of IUGR (less than tenth percentile) and

mild growth delay (tenth to twenty-fifth percentile). It can be noted that in both groups 1 and 2 there is a lower mean birth weight and higher frequency of children born with IUGR (less than tenth percentile) and mild growth delay (tenth to twenty-fifth percentile) among those with a high level of inbreeding ($F \geq 1/64$) ($0.05 < p < 0.10$). Most of the difference, however, can be accounted by the mild growth delay group as there were very few children who were below the tenth percentile. In group 3, no child inbreeding effects can be seen.

Maternal inbreeding. Table VI shows the unadjusted effects of maternal inbreeding levels on mean birth weight and the incidence of IUGR (less than tenth percentile) and mild growth delay (tenth to twenty-fifth percentile). It can be noted that in both groups 1 and 2 there is a tendency for lower mean birth weight at high inbreeding levels ($F \geq 1/64$) but no difference in the frequency of children born at less than the twenty-fifth percentile at different inbreeding levels.

Paternal inbreeding. Table VII shows the unadjusted effects of paternal inbreeding levels on mean birth weight and the incidence of IUGR (less than tenth percentile) and mild growth delay (tenth to twenty-fifth percentile). No significant paternal inbreeding effects can be seen.

Multivariate analysis of inbreeding effects

Length of gestation. Table VIII shows the results of multiple linear regression analysis on mean gestational age and multiple logistic regression on the frequency of deliveries at ≤38 weeks. In this table, groups 1 and 2 are combined. However, similar results are obtained when they are analyzed separately. After simultaneous adjustment of child, mother, and father inbreeding coefficients as well as potential confounding factors (Table VIII), mother's F was found to be a strong predictor of both mean gestational age and the frequency of delivery at ≤38 weeks ($p < 0.001$). Predicted mean gestational ages vary from 39.9 weeks for $F = 0$ (no inbreeding) to 38.3 weeks for $F = 1/16$ (first cousins). Likewise, the predicted proportion of children born at ≤38 weeks varies from 6% for $F = 0$ to 70.1% for $F = 1/16$. However, despite these strong maternal inbreeding effects, it has to be noted the mother's F accounts for about 10% of the variance in gestational age, which suggests that other unknown factors are operating in predicting the length of gestation. On the other hand, child's F was found to be an independent predictor of mean gestational age ($p = 0.01$) but not the proportion of infants born at ≤38 weeks ($p = 0.311$) (Table VIII). The proportion of the variance in gestational age accounted for by the child's F was <5%.

*p <0.05 (simple linear regression of birth weight on mother F).

Therefore, although child inbreeding could be an independent predictor of the length of gestation, our results are equivocal and cannot be confirmed in both types of analyses. Last, not shown in Table VIII is that paternal inbreeding exerted no independent effects on mean gestational age and the risk of early delivery (≤38 weeks).

Intrauterine growth. Table IX shows results of multiple logistic regression analysis on the incidence of intrauterine growth delay (less than twenty-fifth percentile) in groups 1 and 2 combined. However, similar results are obtained when they are analyzed separately. After simultaneous adjustment of child, mother, and father inbreeding coefficients as well as potential confounding factors (Table IX), only child's F was found to be an independent predictor for the risk of being below the twenty-fifth percentile.

Simultaneous analysis of IUGR and prematurity. Fig. 1 shows the results of the log linear analysis of length of gestation (≤38 weeks as outcome) and intrauterine growth (less than twenty-fifth percentile as outcome) in relation to child, maternal, and paternal inbreeding (≥1/64) in groups 1 and 2 combined. Values in Fig. 1 correspond to adjusted odds ratios relating different variables. *Solid lines* correspond to relationships that are statistically significant at the 0.05 level. This analysis indicates that: (1) child inbreeding is associated with a 3.02-fold increase in the risk of being born below the twenty-fifth percentile in weight for gestational age, (2) maternal inbreeding is associated with a 2.77-fold increase in the risk of being born at ≤38 weeks, (3) paternal inbreeding is not a risk factor for either outcomes, (4) there is an association between short gestation and intrauterine growth delay (odds ratio = 3.48), and (5) maternal inbreeding is associated with child inbreeding (odds ratio = 1.90). It is to be noted that the above relationships were not changed by introducing other variables in the model (considered in Tables VIII and IX). Also, although child inbreeding was associated with a 1.65-fold increase in the risk of short gestation, this increase was not statistically significant.

Comment

This study suggests the presence of autosomal recessive genes affecting the length of gestation and intrauterine growth in the Old Order Amish. The main finding of the study, however, is the differential impact of the genetic component on prematurity and IUGR.

*Predicted means were obtained by use of multiple linear regression analysis with gestational age as dependent variable. Independent variables included child, mother, and father inbreeding coefficients (continuous), maternal and paternal ages, birth order, year of birth, father's occupation, sibship history of death, total number of siblings, sex, and growth retardation (less than or equal to the twenty-fifth percentile).

†Predicted percents were obtained by use of multiple logistic regression analysis with binary outcomes ≤38 weeks' versus >38 weeks' gestation. The independent variables are the same ones used in multiple lienar regressions.

‡Child inbreeding effect: $p = 0.01$ on mean gestational age and $p = 0.311$ (NS) on percent ≤38 weeks. Mother inbreeding effect: $p < 0.001$ on mean gestational age and $p < 0.001$ on percent ≤38 weeks.

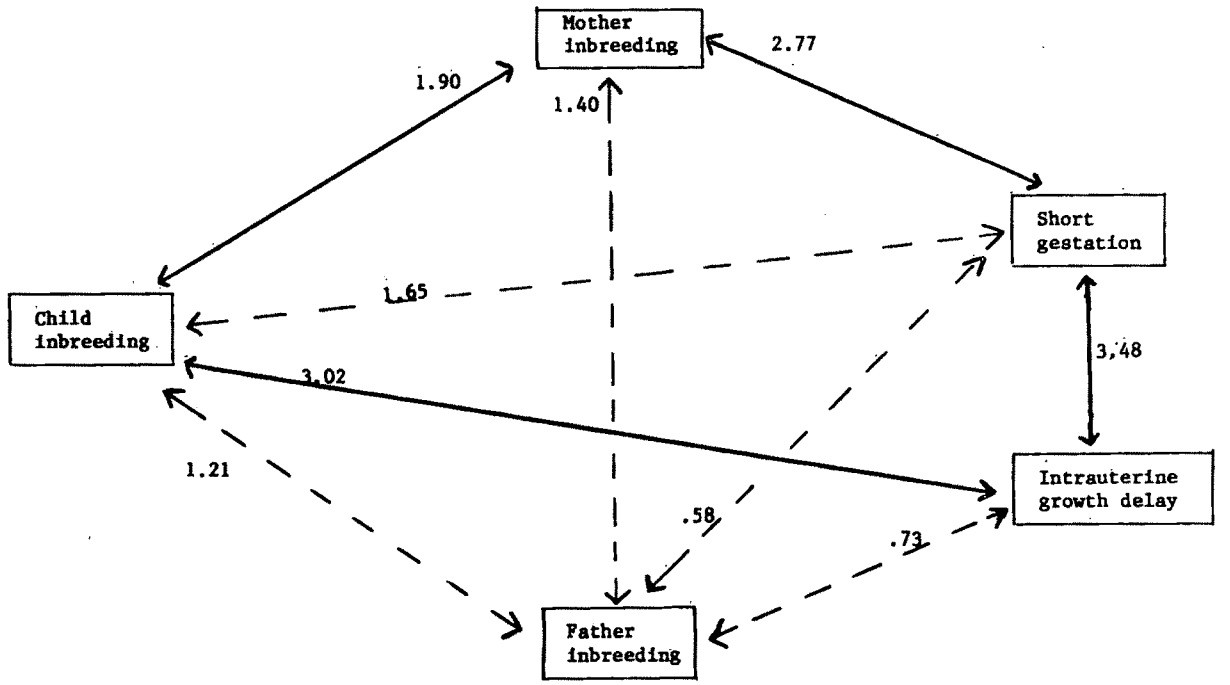

Fig. 1. Log linear analysis of the effects of child, mother, and father inbreeding on gestational age and intrauterine growth. Inbreeding variables were categorized into close inbreeding (≥1/64) versus distant inbreeding (<1/64). Short gestation defined as ≤38 weeks. Intrauterine growth delay defined as less than the twenty-fifth percentile in birth weight for gestational age. Numbers represent adjusted odds ratios relating each two variables. *Solid lines* represent relationships that are significant at the 0.05 level, whereas *dotted lines* represent nonsignificant relationships.

†Child inbreeding effect: p = 0.05. Mother inbreeding effect: p = 0.745 (NS).

The data suggest that while the maternal genotype is associated with a shorter gestation time (as reflected by the maternal inbreeding effect), the fetal genotype is associated with retardation in intrauterine growth (as reflected in the child inbreeding effect). There is a suggestion that the fetal genotype may also be associated with premature birth. However, this effect is not consistent in different analyses and should be confirmed in other studies. Also, the lack of any child or maternal inbreeding effects in group 3 is not entirely surprising since infant deaths constitute a highly selected sample representing less than 2% of all Amish births.[10] In such infants, other factors such as congenital malformations and pregnancy and labor complications are causally associated with both prematurity and IUGR and can mask any inbreeding effects.

The study has several potential limitations. First, birth certificates are known to be incomplete in ascertainment of gestational age. Also, the reliance on last menstrual period is subject to maternal recall and may introduce errors in computation of gestational age. In this study, about 13% of certificates had to be excluded because of unknown gestational age information. However, this can affect our findings only if there is a bias in collecting gestational age data depending on inbreeding levels of mother and child. The existence of such a bias is highly unlikely given the relative cultural

and health care homogeneity of the Old Order Amish. Second, because very few infants met the usual criteria for prematurity (<37 weeks) and IUGR (less than tenth percentile), we had to extend the analysis to include outcomes such as borderline maturity (37 to 38 weeks) and mild growth delay (tenth to twenty-fifth percentile). We view this extension as reasonable given the consistency of findings between the analysis of mean gestational age and the binary variable and also because intrauterine growth can be considered as a continuum rather than a totally discrete entity. Moreover, Johnstone and Inglis[7] found that familial trends in IUGR apply for both the tenth and twenty-fifth percentile cutoffs. Third, because the Amish are highly inbred, the variation in inbreeding coefficient values is limited. For example, no child had an F = 0, and no child was an offspring of first-cousin marriage (F = 1/16). However, this lack of variation of inbreeding values, if anything, tends to reduce the statistical power needed to detect true differences between groups and lead to more conservative findings. Also, a reduction in power will be noted when inbreeding coefficients are used as categorical variables (F > 1.64 versus <1/64) as required by the log linear model. This is not a problem in this study since similar results were obtained in linear and logistic analyses with F values used as continuous or categorical variables.

The significance of this analysis can be viewed along several lines. First, because the Amish have homogeneous characteristics, inbreeding effects are unlikely to be confounded by other factors that may be associated with both inbreeding and low birth weight and, we believe, reflect a true genetic etiology. The lack of adjustment for confounding factors has been a longstanding problem in the interpretation of inbreeding effects in many studies.[10] Since low socioeconomic status tends to be associated with inbreeding in various populations, it needs to be adjusted for before effects of inbreeding on child morbidity and mortality are interpreted. Such an issue has often been overlooked, especially in the early literature on inbreeding.[10] Second, this study is one of few that have analyzed the effects of parental inbreeding in addition to the child inbreeding on disease outcomes. Parental inbreeding information is usually not available in most populations because it requires knowledge of pedigree structure beyond the parents. However, such data are readily available in the Amish multigenerational pedigrees. Third, most studies dealing with genetic analysis of birth weight and with inbreeding effects on birth weight have not examined prematurity and IUGR simultaneously or have relied exclusively on separate analyses of birth weight and gestational age.

How does this analysis compare with other studies of inbreeding effects? Generally, no effect of child inbreeding on gestational age has been found in several studies (see reference 16). However, analysis of inbreeding effects on birth weight has given equivocal results. In Japanese live births, Morton[16] found that child inbreeding had a significant depressing effect on birth weight, which was considered a reflection of intrauterine growth. Other studies found no significant effect of child inbreeding on birth weight. These equivocal findings can be partly attributed to the failure of examining the gestational age component of birth weight. If inbreeding affects intrauterine growth but not the length of gestation, its effect on birth weight may be masked by the proportion of premature infants among those with low birth weight. Another reason for the discrepancies in findings may be related to the extent and duration of inbreeding in the population. With prolonged and intense inbreeding (for example, in India), there may be lowering of equilibrium allele frequencies for lethal genes,[11] thus leading to a smaller observed effect of inbreeding on IUGR (which is associated with a higher risk of death). On the other hand, several analyses of parental inbreeding effects in Japan found no significant maternal or paternal inbreeding effect on prereproductive mortality or growth and development throughout childhood.[10] However, we are not aware of any published parental inbreeding analysis of gestational age and intrauterine growth.

Differences in the role of genetic factors in the etiology of prematurity and IUGR as suggested in this article are also consistent with several analyses that showed a specificity in familial aggregation in prematurity and IUGR. Women who had one infant with IUGR seem to be at higher risk of having another with IUGR but not with prematurity, while women with a premature infant seem to have a higher risk for prematurity in a subsequent pregnancy but not IUGR (see reference 7). However, although these analyses point to the persistence of etiologic factors operating in successive pregnancies, they cannot infer whether such factors are genetic or environmental in nature. Our study shows that the basis for the specificity in familial recurrence is due, at least in part, to a differential genetic component acting on prematurity and IUGR, respectively. Finally, this study reemphasizes the need to consider both prematurity and IUGR in genetic and epidemiologic studies of low birth weight. This will lead to specific characterization of risk profiles associated with one or both entities and ultimately to improved prevention strategies.

Fetal weight estimation formulas with head, abdominal, femur, and thigh circumference measurements

Anthony M. Vintzileos, M.D., Winston A. Campbell, M.D., John F. Rodis, M.D., Roy Bors-Koefoed, M.D., and David J. Nochimson, M.D.

Farmington, Connecticut

Most current sonographic techniques for estimating fetal weight involve measurements of the head, abdomen, and femur length both alone and in combination. The value of the fetal thigh circumference measurement in addition to the head, abdominal, and femur length measurements has not been investigated previously. Eighty-nine patients were scanned within 72 hours of delivery, and the following ultrasonic fetal parameters were obtained in all fetuses: biparietal diameter, head circumference, abdominal circumference, femur length, and thigh circumference. With multiple stepwise regression analysis, the best-fit formulas were developed with one, two, three, four, and five parameters, respectively. The best results were obtained by combining measurements of all five parameters: biparietal diameter, head circumference, abdominal circumference, femur length, and thigh circumference. The mean error of this formula was 6%, the mean deviation 0.3%, and the SD 7.8%. These data suggest that the addition of thigh circumference to measurements of the head, abdomen, and femur length improves the accuracy of fetal weight estimates. (Am J Obstet Gynecol 1987;157:410-4.)

Key words: Estimated fetal weight, thigh circumference

Initial attempts to estimate fetal weight by ultrasound were made on the basis of measurements of individual fetal parameters such as the biparietal diameter (BPD)[1] or abdominal circumference.[2] Weight estimates obtained with abdominal circumference alone have been reported to have an SD between 11.1% and 11.9%.[3] Subsequent reports demonstrated that the accuracy of estimating fetal weight is improved when multiple fetal parameters are used.[3-6] The methods that give reasonably accurate results and are the simplest to apply are those based on the use of two parameters, namely abdominal circumference in combination with the BPD[4, 5] or abdominal circumference in combination with the femur length.[3, 6, 7] Weight estimates obtained with the use of two parameters have been reported to have an SD between 8.2% and 12.9%.[3] Hadlock et al.[3]

reported an improvement in the fetal weight estimates within 7.5% (1 SD) of the actual birth weight by combining measurements of the head (BPD and head circumference), abdomen (abdominal circumference), and femur (length). The better correlation to the actual birth weight with the use of the femur length in addition to head and abdominal measurements was attributed to the strong linear relationship between femur length and crown-heel length.

Because the fetal weight depends not only on head and body dimensions but also on extremity dimensions, it is reasonable to investigate the role of thigh circumference measurement in improving fetal weight estimates. The range of normal values for fetal thigh circumference measurements from 20 to 40 weeks of gestation has been previously reported by our group.[8] The present study was undertaken to determine whether the addition of the thigh circumference to the measurements of the head, abdomen, and femur length could improve the accuracy of in utero fetal weight estimates.

Material and methods

The study included 89 pregnant women. The majority of the patients were transferred to the University of Connecticut Health Center because of preterm labor or other medical complications of pregnancy (i.e., pregnancy-induced hypertension, vaginal bleeding, etc.). The included patients had singleton pregnancies, and in all cases clinical and ultrasound dating (BPD, femur length) were in agreement. The gestational ages were confirmed by Dubowitz scores[9] after birth. All patients delivered within 72 hours of the ultrasound evaluation. Infants with congenital anomalies were excluded.

The ultrasonic measurements were made with a linear array real-time ultrasound (SRT, General Electric Medical Systems Group, Milwaukee, Wisconsin) equipped with a 3.5 MHz transducer. Ultrasound velocity was 1540 m/sec. Freeze-frame capability was available, and on-screen calibers were used for the measurements. The included patients had all five parameters measured: BPD, head circumference, abdominal circumference, femur length, and thigh circumference. The fetal BPD was determined at the level of the thalami and was measured from leading edge to leading edge (outer to inner skull table). The head circumference was determined at the level of the BPD with measurements from outer to outer margins. The abdominal circumference was measured perpendicular to the long axis of the fetal body at the level of the umbilical vein–ductus venosus complex; measurements were obtained from outer to outer border. The femur length was measured according to the technique of O'Brien and Queenan.[10] The thigh circumference was measured according to the technique of Vintzileos et al.[8] The long axis of the femur was first imaged; the transducer was then rotated 90 degrees to obtain a cross-sectional profile of the middle of the thigh at a position that the bone profile was as round as possible and the boundary of the thigh profile was well defined. All circumferences (head, abdomen, thigh) were determined with the formula $D_1 + D_2 \times 1.57$ on the basis of two diameters at right angles to one another. This technique has been demonstrated to give results equivalent to those obtained with a map measurer.[11] In the present study we chose this method to calculate circumferences because the use of diameter measurements and the equation for the circumference of a circle has been shown to result in a more accurate estimated fetal weight than when a map measurer is used.[12] All ultrasound measurements were expressed in centimeters and the birth weights in grams.

As in previous studies,[3-7] fetal weights were best estimated as a logarithmic function of the ultrasonically measured fetal parameters. Polynomial expressions of the fetal parameters were considered up to the fourth degree. All possible interactions of the fetal parameters were considered up to the third degree. The regression analyses calculated were polynomial regressions with the use of one of the parameters at a time and stepwise regressions that considered all five parameters, the powers of each parameter, and all interaction terms of the five parameters.[13] Results included the best models to predict birth weights with one, two, three, four, and five fetal parameters. The accuracy of the models was examined by the mean residual (predicted birth weight minus actual birth weight), the SEM residual, mean absolute residual (absolute value of the residuals), the SEM absolute residual, and the mean percent error. The mean deviation and the SD for each model were also determined according to previously described techniques.[3, 14] In this context the mean deviation is a measure of systematic errors and the SD is a measure of random errors.

Results

The actual birth weights of the 89 newborn infants ranged from 570 to 4678 gm (mean, 2328 gm), and gestational ages ranged from 24 to 42 weeks (mean, 34.9 weeks). BPD measurements ranged from 5.8 to 10.2 cm (mean, 8.2 cm), head circumference measurements from 21.1 to 35 cm (mean, 30.1 cm), abdominal circumference from 18.8 to 38.8 cm (mean, 29.3 cm), femur length from 4.0 to 8.5 cm (mean, 6.5 cm), and thigh circumference from 7.7 to 18.5 cm (mean, 13.1 cm).

The best five models with one, two, three, four, and five parameters are shown in Table I. The best model with one ultrasonically measured parameter used the

Table III. Comparison of fetal weight estimation formulas on the basis of the percentage of cases that the prediction is within ±5% and ±10% of the actual weight

Model	*Percent within 5% of actual weight*	*Percent within 10% of actual weight*
1	26.6	60.7
2	39.5	69.7
3	42.1	75.0
4	32.9	76.3
5	54.0	80.3

abdominal circumference (model 1); the best model with two parameters used a combination of BPD and abdominal circumference (model 2); the best model with three parameters used a combination of head circumference, abdominal circumference, and femur length (model 3); the best model with four parameters used a combination of BPD, abdominal circumference, femur length, and thigh circumference (model 4); the best model with five parameters used a combination of BPD, head circumference, abdominal circumference, femur length, and thigh circumference (model 5).

The accuracy of these five models is illustrated in Table II. On the basis of the definition of residual, the positive residual is indicative of overestimation and a negative residual is indicative of underestimation. As can be seen in Table II, the best results were obtained with model 5 (R^2, 0.9716; mean residual, −6.12; SEM residual, 21.97; mean absolute residual, 137.51; SEM absolute residual, 14.40; mean error 6%; mean deviation, 0.3%; and SD, 7.8%).

The percentage of cases in which the estimated fetal weight was within ±5% and ±10% of the actual birth weight was calculated on the basis of these five models, and the results are shown in Table III. Model 5 gave the best results predicting the actual weight within ±5% in 54% of the cases and within ±10% in 80.3% of the cases.

The data were also analyzed according to actual birth weight groups. The accuracy of the models according to birth weight groups is demonstrated in Table IV. As can be seen in the birth weight group of <1500 gm, all five models gave a systematic overestimation. The mean deviations for models 1-5 were 7.4%, 8.7%, 5%, 7.2%, and 4.7%, respectively. In the birth weight group between 1500 to 2500 gm, all five models gave a systematic underestimation. The mean deviations for models 1-5 were −0.5%, −4.2%, −1.1%, −3.9%, and −1.5%, respectively. For the birth weight group of >2500 gm, models 2 and 4 gave a systematic overestimation (mean deviation, 1.4% for both models), and models 1, 3, and 5 gave a systematic underestimation (mean deviations, −1.6%, −0.3%, and −0.03%, respectively). The variability of the weight estimates (SD) obtained with model 5 was considerably less than that seen with the other models; the SD for weights <1500 gm was 8.7%, SD for weights between 1500 and 2500 gm was 6.4%, and SD for weights >2500 gm was 8.1%.

The analysis of the results of the present study was conducted in accordance with the format of previous investigations[1-7, 12, 14] to permit meaningful comparisons. As such, fetal gender was not considered as a variable in the development of the fetal weight estimation for-

mulas. In addition, the fetal gender may not be known before birth in many cases. Because the knowledge of fetal gender may improve the accuracy of weight estimates, it would be of interest to investigate its role in future studies.

Comment

The results of the present study indicate that the accuracy of estimating fetal weight by ultrasound is improved when multiple fetal parameters are used. The best model with one ultrasonically determined parameters was with the use of abdominal circumference (model 1). This observation is in agreement with the findings of others[2-4] who have also demonstrated that abdominal circumference is the single best index of fetal weight. According to Hadlock et al.,[3] different models that use abdominal circumference alone have an SD between 11.1% and 11.9%. Our model (model 1), which used abdominal circumference alone, was also found to have the same variability of the weight estimates (SD, 11.4%). According to our data, the best model with the use of two ultrasonically determined parameters was the one that used the BPD and abdominal circumference. Models that used BPD and abdominal circumference have been shown to be reasonably accurate and the simplest to apply, since the estimated fetal weight is read directly from tables that have been prepared with computer assistance.[4, 5] In the study by Hadlock et al.,[3] models that used head measurements (BPD or head circumference) in conjunction with abdominal circumference had an SD between 8.7% and 12.9%. Our results with the two best parameters (BPD and abdominal circumference, model 2) were similar in terms of variability of the weight estimates (SD, 10.6%). The model used by Hadlock et al.,[3] which used femur length and abdominal circumference, had a SD of 8.2%.

With three parameters (BPD or head circumference in conjunction with abdominal circumference and femur length), the variability of the weight estimates has been shown[3] to be improved (1 SD 7.6% to 7.7%); model 3 in our present study, which uses three parameters (head circumference, abdominal circumference, and femur length), was also found to improve accuracy as compared with our models 1 and 2. In addition, our results with three parameters were very similar with the data from Hadlock et al.[3]

The accuracy of the use of four parameters (BPD, head circumference, abdominal circumference, and femur length) in the study by Hadlock et al.[3] was not improved substantially as compared with their models that used three parameters; in that study the SD of models that used these four parameters was 7.5%. In our study in the model that used the best four parameters (model 4) the thigh circumference entered the equation; the SD of this model was 8.9%, very similar to that of model 3.

The best model was the one that used all five parameters (model 5). This model had an SD of 7.8%. The accuracy of this model is illustrated in Tables II-IV. In weights <1500 gm, this model gave a systematic overestimation (mean deviation, 4.7%); in gestations be-

tween 1500 and 2500 gm, the model gave a systematic underestimation (mean deviation, −1.5%); and in weights >2500 gm, the model gave a systematic underestimation (mean deviation, −0.03%).

One fetal weight estimation formula that used thigh circumference measurement has been previously presented by Hohler et al.[15] These investigators constructed a formula that used thigh circumference in conjunction with abdominal circumference and femur length to estimate fetal weight. They found that this formula was more accurate than the equation by Warsof et al.[4] and as accurate as the one by Shepard et al.[5]; the investigators recommended the use of this formula when the BPD is unobtainable or when the cephalic index is not within normal limits.

Formulas incorporating thigh circumference measurements may be proven most useful in predicting fetal weight when growth abnormalities are present. Fetal growth aberrations (intrauterine growth retardation or macrosomia) are associated with changes in soft tissue mass, which is decreased in intrauterine growth retardation and is excessive in macrosomia. Pediatric experience has shown that thigh circumference is one of the parameters that reflects soft tissue mass.[16] Our group[8] has also shown that the ultrasonically determined thigh circumference is decreased in fetuses with intrauterine growth retardation and increased in fetuses with macrosomia. It is our opinion that thigh circumference formulas may be helpful in improving the accuracy of fetal weight estimates in growth-retarded and macrosomic fetuses who have quantitative disturbances in the soft tissue mass. The accuracy of this formula in predicting weight in fetuses with normal and abnormal growth is being currently evaluated prospectively at the University of Connecticut Health Center.

In utero ponderal index as a prognostic factor in the evaluation of intrauterine growth retardation

S. Yagel, D. Zacut, S. Igelstein, Z. Palti, A. Hurwitz, and B. Rosenn
Jerusalem, Israel

The in utero ponderal index has become a method of estimating fetal growth. Several methods have been used in the formulation of the in utero ponderal index. In the present study, 1040 pregnant women underwent ultrasonic examination between 24 and 41 weeks of gestation, and the in utero ponderal index was determined by dividing the estimated fetal weight by the third power of the femur length, rendering a relatively constant value of 8.345 ± 2.5 (2 SD). Fifty-one cases were defined as intrauterine growth retardation due to an estimated fetal weight lower than the tenth percentile for gestational age. The in utero ponderal index proved to be a valuable index in the prediction of fetal outcome in those cases of intrauterine growth retardation in which the in utero ponderal index was smaller than 1 SD from the average of 8.345. Fetal and neonatal well-being was clearly compromised when intrauterine growth retardation was associated with a low in utero ponderal index. (AM J OBSTET GYNECOL 1987;157:415-9.)

Key words: Intrauterine growth retardation, ponderal index, ultrasound

Ultrasonic evaluation of fetal weight is imperative for antenatal diagnosis of intrauterine growth retardation (IUGR). The most commonly accepted definition of IUGR is estimated fetal weight below the tenth percentile for gestational age.[1, 2] The accuracy of ultrasonic determination of IUGR in predicting birth weight below the tenth percentile is reported to be up to 96%.[2, 3] An ultrasonic diagnosis of a small fetus might be the result of placental insufficiency or of congenital anomalies causing growth limitation and other abnormal conditions[1] but may also represent a constitutionally small fetus. Furthermore, most methods of ultrasonic diagnosis are scaled to gestational age, while accurate gestational age may not always be accurately established. This fact alone is apt to lead to erroneous diagnosis of IUGR.

For more than 25 years, pediatricians have been implementing Rohrer's ponderal index in evaluating fetal growth impairment.[1] It has been shown to be a useful parameter in qualifying the effect of intrauterine malnutrition on the newborn infant. The ponderal index is defined as birth weight × 100/(crown-heel length),[3] and its mean value varies from 2.25 at 30 weeks of gestation to 2.55 at 38 weeks.[1] Recently, several variations of the ponderal index have been suggested to represent the fetal ponderal index.[5, 6] These indices are based on the fetal femoral length as representing the fetal length[7] and on the fetal abdominal circumference, which is known to be closely related to the fetal weight.[6] The analogous fetal ponderal indices were all found to maintain a constant value between 20 and 40 weeks of gestation, and their importance and usefulness in evaluating fetal growth in high-risk pregnancies lacking established gestational ages were emphasized.

Recently, in utero ponderal index [based on estimated fetal weight/(calculated fetal length^3)] was evaluated as a predictor of IUGR in a group of 113 patients who were delivered of their infants within 72 hours of the ultrasound examination. This method was found to have a sensitivity of 76.9%, a specificity of 82%, and a negative predictive value of 96.4%.[8]

The aim of the present study was twofold: First, we aimed to determine the distribution of a modified intrauterine fetal ponderal index, defined as:

$$\text{IUPI} = \frac{\text{EFW}}{(\text{FL})^3}$$

where EFW is estimated fetal weight given in grams and FL is fetal length given in centimeters, on the basis of a large data set (1040 ultrasonic estimations of fetal weight, performed according to the method of Shepard et al.)[9]

The second aim was to investigate prospectively the value of the in utero ponderal index in cases with estimated fetal weight below the tenth percentile during the second half of pregnancy.

Material and methods

A total of 1040 gravid women underwent an ultrasonic evaluation of pregnancy between the twenty-

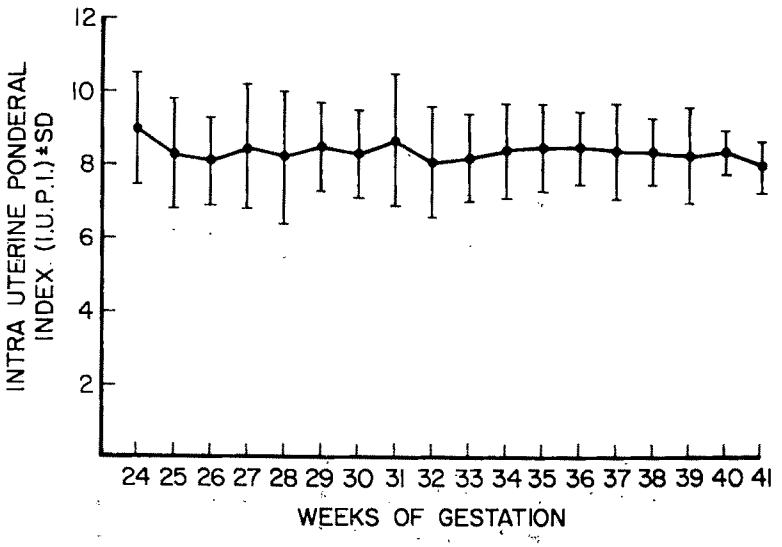

Fig. 1. Distribution of in utero ponderal index in 1040 gestations between 24 and 41 weeks.

fourth and forty-first weeks of gestation, with the use of a linear, phased array, real-time Aloka Echo camera, Model SSD-256, with a freeze frame and electronic calipers. All examinations were performed by the same operator. The 1040 patients were selected on the basis of a definitely dated last menstrual period and a history of regular menstrual cycles, with ultrasonically confirmed gestational age prior to the twenty-second week of pregnancy. Multiple gestations and those with evident malformations were excluded from the study.

Biparietal diameter measurements were obtained at the thalamic level according to the technique described by Sabbagha and Highey.[10] Femoral length measurements were carried out by use of the technique suggested by Mahoney and Hobbins.[11] Measurements were repeated until reproducible within a 1 mm range at least three times, then averaged and recorded. Abdominal circumference was calculated according to the technique described by Ott et al.[12] Fetal weight was calculated by means of the formula proposed by Shepard et al.[9] The in utero ponderal index was then calculated with the following equation:

$$\text{IUPI} = \frac{\text{EFW (in grams)}}{(\text{FL})^3 \text{ (in centimeters)}}$$

We chose the fetal length in the above formula in an attempt to be as similar as possible to the original neonatal ponderal index of Rohrer. In 51 patients (4.9%), the estimated fetal weight was found to be below the tenth percentile for gestational age, thus establishing an ultrasonic diagnosis of IUGR. The in utero ponderal index was calculated at the time of diagnosis but was withheld from the treating physicians. These pregnancies with IUGR were thoroughly followed up throughout delivery in the following manner: (1) Repeated ultrasonographic evaluation, including estimated fetal weight, placental grading, and biophysical scoring according to Manning and Morrison[13] (amniotic fluid volume, fetal tone and body movements, fetal breathing movements, and nonstress testing from the thirty-second week of pregnancy onward), was performed at intervals of 2 to 3 weeks up to the thirty-sixth week of pregnancy, and then at 5-day intervals. (2) Possible underlying maternal causes were sought, and tests were taken for markers of collagen disease, recent viral infections, anemia, diabetes mellitus, hypertensive disorders, renal disorders, etc. (3) The umbilical arterial wave pulse was recorded according to Schulman et al.,[14] in some of the patients, for determination of the systolic/diastolic ratio. (4) Examination of the neonate included Apgar scoring; blood testing for complete blood count, electrolytes, calcium, glucose, and thyroid hormone levels; Dubowitz scoring; determination of the ponderal index[4] according to Rohrer; and brain sonography for evaluation of intraventricular hemorrhage.

Results

Among the 1040 patients undergoing ultrasonic evaluation between 24 and 41 weeks of gestation, 93% had a completely normal pregnancy. The remaining 7% comprised patients with IUGR, polyhydramnios, premature rupture of the membranes, abruptio placentae, and intrauterine fetal death. Gestational age was estimated in each case, on the basis of biparietal diameter and fetal length,[15] and was found to be compatible with gestational age in 95% of the cases. In 2% of the cases, estimated age was smaller than clinical age by >2 SD, and in half of these cases, a decreased amount of amniotic fluid was observed, namely, pockets measuring

§There were two intrauterine fetal deaths in the group of 21 patients with abnormal intrauterine ponderal indexes.

≤5 cm at the largest dimension. In 3% of the cases, estimated age was greater than clinical age by >2 SD. In 22% of these, polyhydramnios was evident, with no apparent anatomic cause.

The in utero ponderal index, calculated via the formula given, is clearly seen to maintain a relatively constant value of 8.345 during the second half of gestation, as exemplified by Fig. 1.

The second study group comprised 51 cases suspected to have IUGR as diagnosed by ultrasonic examination. Thirty of these fetuses were found to have a normal in utero ponderal index, while 21 had an abnormal in utero ponderal index that was ≥1 SD below the mean. Fetal and neonatal outcomes, together with clinical descriptions of the compromised neonates, are summarized in Tables I to III.

The group with an abnormal in utero ponderal index was found to have a higher incidence of a low biophysical score (≤6), namely, 47.6% versus 16.6% in the normal group, and a higher incidence of intrapartum fetal distress (23.8% versus 6.6%). As might be expected, there was a higher rate of delivery by cesarean section in the abnormal group (33.3% versus 10%) and of intrauterine fetal death (9.5% versus 0%). In seven patients in the abnormal group, Doppler determination of the umbilical artery systolic/diastolic ratio was performed and found to be >3 : 1 in four. None of the nine patients in the normal group undergoing the examination showed abnormal results.

A low Apgar score of ≤7 at 5 minutes post partum was more common in the abnormal group (26.3% versus 0%), as were abnormal results of blood biochemistry studies (36.8% versus 6.6%). Not one case of intraventricular hemorrhage was diagnosed in the normal group as opposed to four cases (21%) in the abnormal group. There were two neonatal deaths among the abnormal group and none in the normal group. A postpartum diagnosis of neonates that were small for gestational age was assigned in 47.4% of the abnormal in utero ponderal index group as opposed to only

Negative predictive value	= 96.7%
Accuracy	= 78.4%
Prevalence	= 23.5%

16.5% in the group with a normal in utero ponderal index. A low neonatal ponderal index (1 SD below normal) was predominant in the abnormal group, manifesting itself in 47.4% of the cases, while only 3.3% of the normal group had a consequently low neonatal ponderal index.

Table IV summarizes the prognostic ability of the in utero ponderal index in cases of suspected IUGR.

Comment

An ultrasound diagnosis of IUGR in the latter half of pregnancy presents the problem of consequent follow-up and treatment. Small for gestational age newborn infants are known to suffer from increased perinatal morbidity and mortality, but, on the other hand, antenatal ultrasound diagnosis of IUGR has failed to exhibit a significant correlation with a compromised fetal outcome.[16] This somewhat surprising fact may be related to several factors: (1) Ultrasound-determined estimated fetal weight is well known to have an error between 4% and 15%,[12] and even the slightest inaccuracy in weight estimation may make the difference between a diagnosis of small for gestational age and one of appropriate for gestational age. (2) Many infants, although below the tenth percentile of weight for gestational age, are nonetheless normal and healthy. (3) A misdiagnosis of IUGR is sometimes due to an erroneous gestational age.

Two facts clearly stand out in our present study: First, the in utero ponderal index maintains a constant value, a fact that is in accordance with recent reports[5, 6]; second, the in utero ponderal index clearly differentiates between two distinct groups of fetuses and may serve as a guide in evaluating the ultrasonic data and in deciding on subsequent follow-up and treatment.

Pregnancies with a diagnosis of small for gestational age with a normal in utero ponderal index had the same

outcome as that in the general population. Most (83.5%) of these infants had birth weights within normal limits, and indeed in 80% a normal estimated fetal weight was established during subsequent ultrasound examinations in the follow-up period. This fact probably represents the inaccuracy of ultrasound weight estimation combined with the rigid cutoff point at the tenth percentile. A total of 16.5% of the pregnancies were concluded with the birth of a small for gestational age but otherwise normal baby, with a normal ponderal index; these babies are constitutionally small. Only one newborn infant had evidence of malnutrition, exemplified by a low ponderal index.

On the other hand, the perinatal outcome of the group with an abnormal in utero ponderal index was devastating. Among the 21 pregnancies, there were two intrauterine fetal deaths, two neonatal deaths, and four cases of intraventricular hemorrhage. Five newborn babies had low Apgar scores (≤ 7), and nine of 19 had a ponderal index lower than the tenth percentile for gestational age. The abnormal in utero ponderal index also proved to correlate with findings indicative of placental insufficiency and of fetal compromise; four of seven patients had Doppler-measured umbilical artery systolic/diastolic ratios of $>3:1$, 10 of 21 had a decreased amniotic fluid volume, and eight had a high placental grading (Grade III) before delivery. A biophysical profile score of ≤ 6 was found in 10 of 21 pregnancies with low in utero ponderal indexes, five exhibited intrapartum fetal distress, and six were delivered by cesarean section.

The fact that the in utero ponderal index was found to maintain a constant value throughout the second half of pregnancy is in obvious discordance with the nomograms describing neonatal ponderal index according to gestational age, which show a gradual increase in the ponderal index from 30 to 38 weeks of gestation.[1] This discrepancy might be explained by the fact that the data base in designing the nomograms was most probably biased by intrauterine growth retardation in premature newborn infants with a low ponderal index. Our relatively constant in utero ponderal index was derived from ultrasound determinations in pregnancies, the majority (95%) of which were normal, and is in accordance with that of others.[5, 6]

The value of determining the in utero ponderal index in cases of suspected IUGR is summarized in Table IV. In our study group, a fetus in the third trimester with an ultrasound diagnosis of IUGR and an abnormally low in utero ponderal index had a 50% chance of being malnourished and a 30% chance of suffering some kind of severe morbidity or dying. Conversely, a normal in utero ponderal index, in the presence of IUGR in this group, was associated with a normal outcome in 96.7% of the cases.

In conclusion, although the sensitivity and the positive predictive value of the described method do not support it as a diagnostic screening procedure, the data do indicate that if IUGR is diagnosed then an abnormal in utero ponderal index places the fetus in a particularly high-risk category. However, this method may help in the follow-up of fetuses believed to have IUGR.

Nerve entrapment after Pfannenstiel incision

William C. Sippo, M.D., Captain, MC, USA, Anne Burghardt, M.D., Major, MC, USA, and Alphonse C. Gomez, M.D., Colonel, MC, USA

El Paso, Texas

In a 16-month period, nine cases of iliohypogastric nerve entrapment were diagnosed in patients who had undergone a Pfannenstiel incision. Three patients experienced total relief with nerve blocks alone; four patients required surgical interruption of the iliohypogastric nerve to attain total relief; two patients received significant symptomatic relief with injection and desired no further treatment. The presentation, diagnosis, treatment, and prevention of entrapment of the iliohypogastric nerve as a complication of the Pfannenstiel incision are presented and discussed. (AM J OBSTET GYNECOL 1987;157:420-1.)

Key words: Iliohypogastric nerve, nerve entrapment, Pfannenstiel incision

The purpose of this article is to identify iliohypogastric nerve entrapment as a common complication of the Pfannenstiel incision and to present an approach to the diagnosis, treatment, and prevention of this complication.

Material and methods

During the 16-month period September 1, 1984, to December 31, 1985, nine patients with the complaint of lower abdominal pain, a history of a Pfannenstiel incision, and a negative workup for their symptoms were evaluated with a diagnostic ilioinguinal-iliohypogastric nerve block.

Six patients had had one procedure and three had had multiple procedures via Pfannenstiel incision.

Seven patients noted the onset of symptoms within 3 years, and two patients had symptoms more than 10 years after the last procedure.

The patients' histories were strikingly similar, being characterized initially by activity-induced, intermittent sharp pain that emanated from the incision site and radiated into the labia and/or upper inner aspect of the thigh and then over weeks to months progressed into a constant dull, burning pain within this same distribution.

The patients were placed in a supine position, with the region from the umbilicus to the upper thigh exposed on the side involved. A 3-inch, 25-gauge spinal needle was guided with a gloved hand beneath the external oblique aponeurosis at a point 1 inch medial and 1 inch inferior to the anterior superior iliac spine. With a 2:1 mixture of 0.5% bupivacaine and 1.0% lidocaine without epinephrine, 1 ml was deposited at this site. The needle was advanced toward the pubic tubercle, and on its withdrawal 3 ml of the mixture was injected with steady, even pressure. Without removal of the needle, it was redirected such that, in three or more passes, a fan-shaped deposition of anesthetic was accomplished (the last injection being perpendicular to the midline) (Fig. 1). The needle was directed beneath the rectus fascia when it was encountered.

The patients were evaluated on a weekly basis and underwent reinjection if symptoms recurred. Patients whose symptoms recurred after a third injection were considered for surgical intervention.

Results

All nine patients reported immediate relief of symptoms after injection.

Total resolution of symptoms was achieved in one patient after one injection and in two patients after a second injection; these patients remained symptom free on 6-month follow-up and required no further treatment.

Two patients experienced a significant alteration of their discomfort with the block and desired no further intervention. On follow-up these patients related occasional intermittent symptoms, which they tolerated.

The four remaining patients received only transient relief after each of the three injections and underwent surgical exploration.

The first had a palpable neuroma within the rectus sheath involving a branch of the iliohypogastric nerve. Symptoms resolved after excision of the neuroma.

The second patient had surgical interruption of the ilioinguinal nerve proximal to the area of the original incision without complete relief of symptoms. Reexploration was performed subsequently with the patient under local anesthesia, at which time the iliohypogastric nerve was identified as the source of symptoms. A

From the Department of Surgery, William Beaumont Army Medical Center.

Reprint requests: Captain W. C. Sippo, MC, Department of Surgery, William Keller Army Hospital, West Point, NY 10996.

1 cm portion of the nerve was excised and the proximal and distal ends were ligated. This patient experienced complete relief.

The last two patients likewise underwent exploration while under local anesthesia and had resolution of symptoms after interruption of the iliohypogastric nerve as described above.

Comment

Our ability to relieve symptoms in all nine patients with the ilioinguinal-iliohypogastric nerve block and the results of our surgical intervention suggest that the nerve entrapment syndrome associated with the Pfannenstiel incision is due to injury of the iliohypogastric nerve.

Nerve entrapment may result from incision of a nerve with formation of a neuroma, from incorporation of a nerve by suture in the closure of the fascia, or from the tethering and constriction of a nerve in the surrounding scar that results from the normal healing process.[1]

Injury to the iliohypogastric nerve is more likely to occur either when the fascial incision extends beyond the lateral edge of the rectus sheath and into the substance of the internal oblique muscle where this nerve runs or when the corners of this fascial incision are closed with widely placed sutures, which may incorporate distal branches of the nerve in the closure.

There are two formally described methods of extension of the Pfannenstiel incision, both of which emphasize that the incision should be extended through the external oblique aponeurosis only and not involve incision of the internal oblique muscle.[2] In this way injury to the nerve may be avoided.

Closure of the Pfannenstiel incision does not require widely placed corner sutures to prevent incisional hernia. Injury to the nerve from closure is therefore easily avoidable by carefully placed sutures limited to the fascia.

The ilioinguinal-iliohypogastric nerve block is an important diagnostic tool in the assessment of patients with abdominal wall pain after Pfannenstiel incision. If the block relieves a patient's symptoms, then entrapment may be implicated and treatment initiated without more costtly and invasive workup.

As demonstrated by our results, the ilioinguinal-iliohypogastric nerve block is also an important therapeutic tool in the treatment of the nerve entrapment associated with Pfannenstiel incision.

Although the true incidence of this entity is unknown, the number of patients we identified with this syndrome in just 16 months suggests that this is a common complication of the Pfannenstiel incision that will be identified if actively sought.

In summary, entrapment of the iliohypogastric nerve is a common complication of the Pfannenstiel incision.

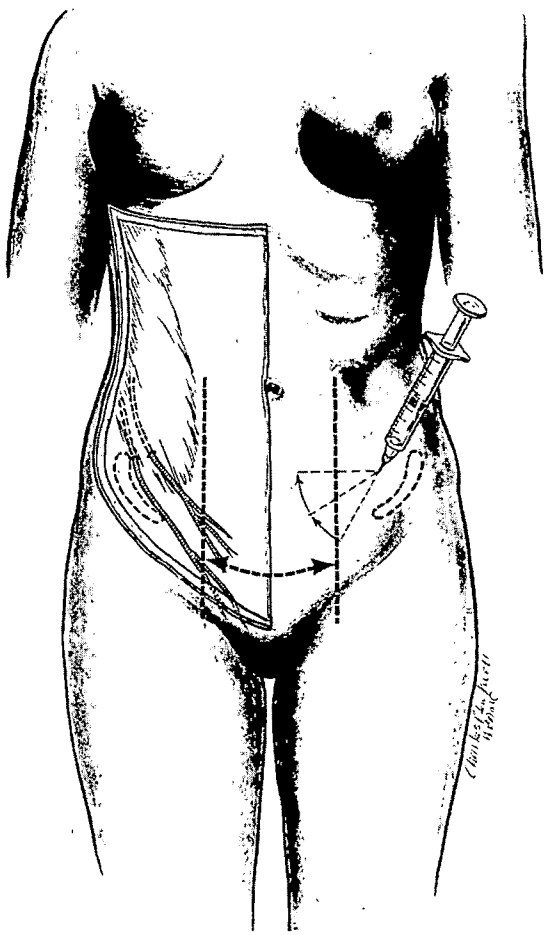

Fig. 1. The courses of the ilioinguinal nerve (lateral) and the iliohypogastric nerve (medial) are depicted on the *left*. The *vertical dashed lines* represent the borders of the rectus muscles and the *transverse dashed line* depicts the location of the Pfannenstiel incision. The pattern of injection for the nerve block is demonstrated on the *right*.

Patients present with vague, lower abdominal, burning pain in the region of the incision; this pain may radiate to the labia or upper inner aspect of the thigh. Relief of symptoms after ilioinguinal-iliohypogastric nerve block is diagnostic of the entrapment and may preclude an unnecessary costly workup. Failure of recurrent blocks to relieve the symptoms permanently suggests that a surgical interruption of the nerve is warranted.

Nerve injury may be minimized by both limiting the extension of the Pfannenstiel incision beyond the confines of the rectus sheath to the external oblique aponeurosis and avoiding the wide placement of sutures in the closure of the anterior fascia at its corners.

Treatment of polyhydramnios with prostaglandin synthetase inhibitor (indomethacin)

Dominique Cabrol, M.D., Robert Landesman, M.D., Joel Muller, M.D., Michele Uzan, M.D., Claude Sureau, M.D., and Brij B. Saxena, Ph.D., D.Sc.
New York, New York, and Paris, France

Polyhydramnios, which is caused by an excess of amniotic fluid, was diagnosed uniformly in eight patients by ultrasound examination and clinical symptoms, namely, premature uterine contraction, abdominal pain, and respiratory discomfort that resulted from excessive pressure on the diaphragm. Fetal anomalies incompatible with extrauterine existence were excluded by serum α-fetoprotein levels, repeated sonography, amniocentesis, and chromosomal analyses. Patients were treated with 2.2 to 3.0 mg of indomethacin/kg body weight/day. The treatment was started at an average gestational age of 24 ± 0.5 weeks and continued for 2 to 11 weeks. All patients had significant improvement with a simultaneous reduction in amniotic fluid volume, fundal height, and umbilical perimeter. All patients were delivered satisfactorily at an average of 39 weeks' gestation. The fetuses were within the normal body weight range of 2750 to 3600 gm and showed normal development during the neonatal period of 2 to 6 months. Before delivery without indomethacin, the polyhydramnios reformed. Adverse effects or intolerance to the drug was avoided by either a reduction in the dose or cessation of indomethacin therapy. Our studies suggest that indomethacin therapy is an effective way to manage pregnancy complicated by polyhydramnios. (Am J Obstet Gynecol 1987;157:422-6.)

Key words: Polyhydramnios, indomethacin, prostaglandins

Prostaglandins E_2 and F_2 are important in the regulation and maintenance of vascular tone of the blood vessels. In the lamb, calf, and goat, prostaglandins relax the pulmonary vessels and the ductus arteriosus. On the other hand, prostaglandin inhibitors such as indomethacin and salicylates increase the pulmonary vascular resistance and constrict the ductus arteriosus, which result in the elevation of the right ventricular pressure and may cause subendocardial ischemia and calcified lesions in the tricuspid valve papillary muscle and thus tricuspid insufficiency. Newborn infants may experience hypoxemia, cardiomegaly, and right to left shunting through either the foramen ovale or the ductus arteriosus. Other investigators have noted few abnormalities in newborn infants whose mothers were treated cautiously with indomethacin in lower doses.

Polyhydramnios results in poor fetal prognosis, especially during the second trimester. There is about a 30% fetal mortality rate because of premature rupture of the membranes and delivery of a fetus weighing between 500 and 700 gm. The patients are managed by repeat transabdominal amniocentesis under tocolytic treatment and withdrawal of fluid. Multiple punctures frequently result in infection or premature rupture of the membranes. The therapeutic use of prostaglandin synthetase inhibitors decreases the amniotic fluid volume and prevents premature labor.[1,2] This approach is based on the known contribution of fetal urinary flow in the production of amniotic fluid and a decreased rate of urinary flow in the premature fetus treated with indomethacin for patent ductus arteriosus.[3,4] In addition, pregnant animal models and women treated with indomethacin for premature birth developed oligohydramnios.[5,6] Therefore indomethacin was chosen to treat polyhydramnios in eight patients.

Material and methods

The patients enrolled in the study had definite clinical polyhydramnios as determined by a fundal height more than 3 cm above that at the normal gestational age (Table I) and confirmed by ultrasonography. Polyhydramnios was defined in our study by the presence of the largest pocket of amniotic fluid at a depth of 8 cm.[1,2] Polyhydramnios was associated with abdominal pain, respiratory discomfort, and premature uterine contractions. Fetal anomalies incompatible with extrauterine existence were excluded by ultrasonography. Karyotype and α-fetoprotein determinations in the aliquot of 20 ml of amniotic fluid aspirated by transab-

Table I. Gestational age, fundal height, and etiology at the time of diagnosis of the polyhydramnios

Patient No.	Diagnosis of polyhydramnios		
	Gestational age (wk)	Fundal height (cm)	Etiology
1	21.5	24	None
2	24	30	Chemical diabetes
3	33	31	None
4	34	33	None
5	28.5	29	Chemical diabetes
6	28	28	Chemical diabetes
7	26	27	Chemical diabetes
8	31	32	None

dominal amniocentesis were used to exclude encephaloceles. The patients signed an informed consent form.

Eight patients, numbered 1 through 8, were treated with indomethacin for polyhydramnios. Patient No. 2 with polyhydramnios had a premature delivery at 28 weeks with neonatal death in 1981 and a late abortion at 26 weeks with a second neonatal death in 1982. Patient No. 4 had polyhydramnios but was successfully delivered of a full-term female fetus weighing 3400 gm. Four patients, namely, Nos. 2, 5, 6, and 7, had chemical diabetes, and the other four had no known maternal or fetal disease (Table II). Treatment with indomethacin began in all eight patients between 24 and 35½ weeks of gestation and at an average gestational age of 30.1 + 0.5 weeks (Table III). Patient ages ranged from 25 to 39 years, and parity was from 1 to 4, as shown in Table II. Indomethacin was administered either orally as tablets or as vaginal suppositories at a dose of 2.2 to 3.0 mg/kg body weight/day. Treatment was usually stopped between 35 and 38 weeks, and optimal care was taken to sustain the pregnancy by providing complete bed rest and if necessary by the administration of β-mimetic drugs orally for 1 week.

The effects of indomethacin therapy were evaluated daily to determine (1) a decrease in maternal symptoms and uterine contractions, (2) measurement of fundal height and umbilical circumference, and (3) weekly ultrasonographic findings to monitor fetal growth and development, as well as the approximate volume of amniotic fluid. The technique of quantitatively measuring the amniotic fluid volume consisted of measuring the depth of the largest pocket during the second half of the pregnancy, and the polyhydramnios was arbitrarily classified on the basis of the clinical impression gained while the biophysical examination of the uterine contents as described by Chamberlain et al.[7] was performed as follows: (1) >1 cm as grade 1, oligohydramnios; (2) 1 to 3 cm as grade 2, decreased fluid; (3) 3 to 8 cm as normal grade 3; and (4) >8 cm as grade 4, polyhydramnios. If under treatment severe oligohydramnios or complete interruption of fetal urinary flow developed, the dose of indomethacin was either decreased or the therapy was discontinued. Patients were evaluated for other causes of polyhydramnios such as hyperglycemia, rhesus blood grouping, irregular agglutinins, toxoplasmosis, and rubella antibodies during the course of treatment with indomethacin.

Results

As shown in Table I, the diagnosis of polyhydramnios was confirmed between 21.5 and 34 weeks by sonogram in all eight patients. Table III shows that the longest duration that indomethacin was tolerated for was 11 weeks (patient No. 2) and the shortest duration was only 2 weeks (patient No. 4). Table IV illustrates that the deliveries were normal, spontaneous, vaginal, and at an average gestational age of 38.6 + 1.6 weeks with an Apgar score of 5 for 1 minute and 10 for 5 minutes. Patient No. 1 had a cesarean because of acute fetal distress. All eight infants weighed between 2750 and 3600 gm at birth. Careful examination during the neonatal period (2 to 6 months) revealed that all physical findings were within normal limits. There were no premature deliveries.

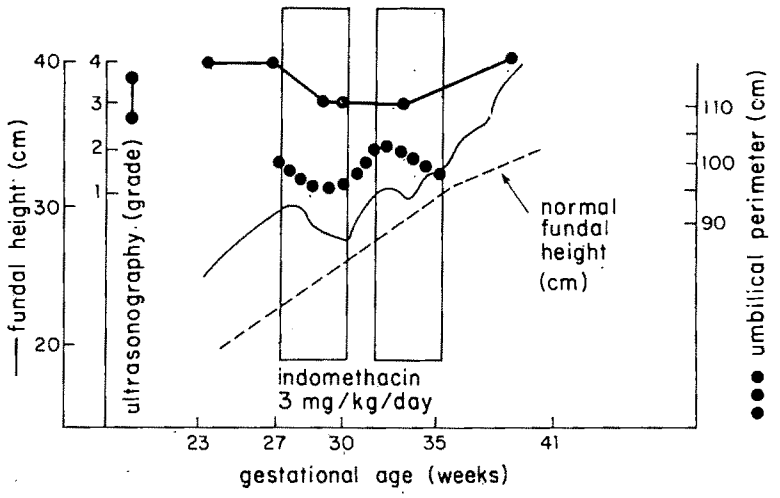

Fig. 1. Fundal height, umbilical perimeter, and qualitative measurement of amniotic fluid volume in patient No. 1 whose polyhydramnios was treated with indomethacin (3 mg/kg/day). *Dashed line* indicates normal fundal height.

Table IV. Delivery and neonatal status in the eight cases of polyhydramnios treated with indomethacin

	Delivery		*Infant*

8	39	Normal delivery	M	3600	9-10	Normal

*Cesarean section for acute fetal distress during labor.

†Physical examination during neonatal period and at 2 or 6 months.

As shown in Fig. 1, indomethacin was administered to patient No. 1 at a dose of 3 mg/kg/body weight/day from 27 to 30 weeks and from 32 to 35 weeks in patient No. 1. After the administration of indomethacin for 10 days, there was a decrease in maternal symptoms. The uterine contractions ceased, and fundal height and umbilical circumference were decreased with normal fetal growth as confirmed by ultrasonography. The normal fundal height dropped while on indomethacin and reversed while indomethacin was withdrawn from 30 to 32 weeks. When the indomethacin was continued as long as 35 weeks, fundal heigh was maximal. The umbilical perimeter did not rise while the patient took indomethacin whereas the grade of amniotic fluid volume dropped. After cessation of indomethacin therapy, the grade of the amniotic fluid rose back to ½ cm. The patient delivered satisfactorily at 39 weeks' gestation; however, polyhydramnios was reformed. To avoid fetal distress, a cesarean was performed, and the Apgar score was 5 at 1 minute and 10 at 5 minutes. The infant weighed 3230 gm. Fig. 2 demonstrates the effects of indomethacin over a 2-week period in patient No. 5. The ultrasonographic grade of amniotic fluid volume dropped from 4 to 2 cm, and the fundal height dropped to less than the average. The umbilical perimeter was reduced from 94 to 90 cm. The patient delivered at 37 weeks' gestational age. The fetus weighed 2750 gm and had an Apgar score of 9 at 1 minute and 10 at 5 minutes. In patient No. 8 (Fig. 3), indomethacin was administered from weeks 31 to 38. The amniotic fluid volume, the umbilical perimeter, and the height of the fundus decreased. As soon as indomethacin was stopped, the amniotic fluid rapidly increased. At the time of delivery (39 weeks' gestation), the polyhydramnios had again recurred. However, this fetus was the largest of the eight fetuses (3600 gm) and had an Apgar

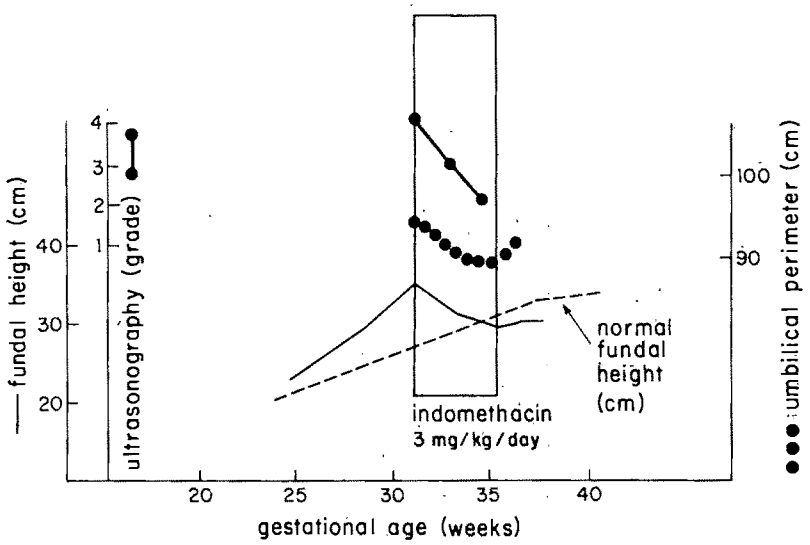

Fig. 2. Fundal height, umbilical perimeter, and qualitative measurement of amniotic fluid volume in patient No. 5 whose polyhydramnios was treated with indomethacin (3 mg/kg/day). *Dashed line* indicates normal fundal height.

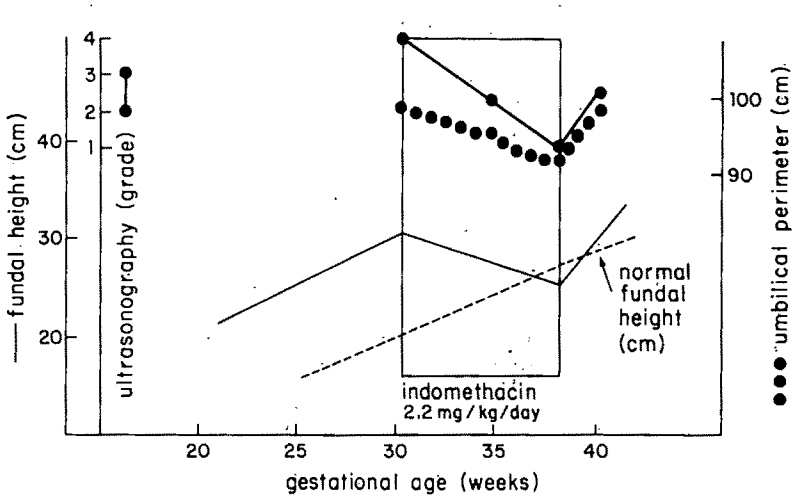

Fig. 3. Fundal height, umbilical perimeter, and qualitative measurement of amniotic fluid volume in patient No. 8 whose polyhydramnios was treated with indomethacin (2.2 mg/kg/day). *Dashed line* indicates normal fundal height.

score of 9 at 1 minute and 10 at 5 minutes. The indomethacin successfully prevented prematurity at 31 weeks and produced a mature infant at 39 weeks.

Comment

In the present study, indomethacin reduced the polyhydramnios in all eight patients. The reduction in the polyhydramnios, which was determined by measuring fundal height and umbilical perimeter, was noted by sonography after a week of therapy. The indomethacin reduced the polyhydramnios by reducing urinary flow and also minimized the amount of fluid produced by the amnion and chorion. Indomethacin was stopped during weeks 35 to 37 to prevent prematurity. We obtained improved clinical and ultrasonographic parameters in all eight patients and were able to avoid premature delivery. The fetuses were of normal size and all weighed more than 2500 gm.

The impact of prostaglandin synthetase inhibitors on amniotic fluid dynamics is not known. It is postulated that they probably decrease fetal urinary output[5, 6] or act on amniotic fluid reabsorption via the lungs.[8] Kitterman and Liggins[9] demonstrated that prostaglandin synthetase inhibitors increase fetal respiratory movements. Indomethacin could also act on fetal membranes, since these tissues, which perhaps play a role

in water transport, contain large amounts of prostaglandins. To elucidate the mechanism of action of indomethacin, more accurate quantitation of amniotic fluid volume and measurement of fetal urinary output before and during treatment as described by Campbell et al.[10] are required.

The risk of treating polyhydramnios with prostaglandin synthetase inhibitors is the generation of fetal anomalies that may contraindicate treatment with this drug. The risk may be minimized by repeated ultrasonographic examinations and frequent karyotyping and regulating the dose of the indomethacin. There was no premature closure of the ductus arteriosus. Long-term follow-up of indomethacin-treated infants has shown no residual effects on renal or cardiopulmonary function.[11] Risks could also be minimized by discontinuation of the drug at 35 weeks of gestation and postponement of delivery for at least 1 week at the end of treatment to prevent complications after delivery in patients treated with indomethacin.[12] Indomethacin-induced oligohydramnios or an interruption of fetal urinary flow, a complication described by Veersema et al.,[13] could be avoided by a decrease in the dose or discontinuation of the treatment. When the indomethacin therapy was terminated, the polyhydramnios reaccumulated, which might have initiated labor by distending the uterus and might have resulted in rupture of the membranes. Prostaglandin synthetase inhibitors, however, seem to be effective and a convenient mode of treatment of polyhydramnios. The risk to benefit ratio may depend on the clinical judgment of specific circumstances.

Human leukocyte antigen associated with endometrial carcinoma with a new classification of endometrial carcinoma based on its etiology

Tatsuya Kanuma, M.D., and Masao Igarashi, M.D., Ph.D.
Maebashi, Japan

To elucidate the relationship between endometrial carcinoma and the constitution, HLA antigen typing (A-locus, 13; B-locus, 20; C-locus, 6; DR-locus, 9) was investigated in 74 patients with endometrial carcinoma. A significant increase in two HLA antigens, Cw7 and DRw8, was demonstrated, but there was no intimate correlation between Cw7 or DRw8 and the three complications commonly associated with endometrial carcinoma—diabetes mellitus, obesity, and hypertensive disease. On the basis of these results, a new classification of endometrial carcinoma was proposed as follows: type A is positive Cw7 or DRw8 group; type B is negative for Cw7 and DRw8 and positive for the complications mentioned; type C is negative for Cw7 and DRw8, negative for the complications mentioned, and positive for DR 5; type D is a non-A, non-B, and non-C type. (Am J Obstet Gynecol 1987;157:427-32.)

Key words: Endometrial carcinoma, HLA antigen

Accumulated evidence suggests that endometrial carcinoma is often associated with specific complications[1-5] such as diabetes mellitus, obesity, hypertensive disease, and hyperestrogenism and that there are some families with a high occurrence of endometrial carcinoma.[6] One of the best ways to investigate hereditary or genetic cause of diseases is HLA antigen typing. Recently a high risk of endometrial carcinoma in Caucasian women with HLA-Aw23 was reported,[7] but unfortunately the investigation of HLA typing was limited to A, B, and C locus. This study included extensive HLA-A, B, C, and DR typing to elucidate the possibility of the existence of special types of HLA antigens in Japanese patients with endometrial carcinoma and the relationship to these complications.

Material and methods

Patients. Seventy-four patients with endometrial carcinoma that was confirmed by histologic examination were investigated on HLA typing and complications, such as diabetes mellitus, obesity, and hypertensive disease. Among these 74 patients, 53 underwent operation at the Gunma University Hospital, and the remaining 21 patients had operations at the Tohmo Cancer Center Hospital, Gunma, Japan. The age range of these patients was from 29 to 74 years, with a median of 54. Of these patients 40.5% were obese, 23.0% had diabetes mellitus, and 18.9% had hypertensive disease.

HLA typing. Twenty milliliters of heparinized blood was obtained from each patient. Lymphocytes were separated from blood samples by means of a Ficoll-Conray density gradient. The B-lymphocytes and T-lymphocytes were separated by the nylon-wool column procedure. With T-lymphocytes, HLA-A, HLA-B, and HLA-C antigens were determined by the National Institutes of Health standard two-stage microcytotoxicity method.[8] HLA antisera of 13 alleles of the A locus, 20 alleles of the B locus, and six alleles of the C locus were purchased from the Hoechst Company, Marburg, West Germany. Each lymphocyte preparation was adjusted to 1000 cells per microliter to consist of at least 90% viable lymphocytes. Lymphocytes were incubated with each of the antisera for 30 minutes at 15° to 25° C. Five microliters of rabbit complement was added to each well, and the incubation was continued for 60 minutes. Two microliters of eosin was then added, and the incubation was terminated by the addition of 10% formaldehyde. The plates were examined by phase microscopy to quantitate cell viability. A positive reaction was regarded as one that showed the presence of eosin in more than 80% of the cells, indicating cell death caused by antigen-antibody reaction. To test for 39 specific antigens, 101 alloantisera (33 for A locus, 55 for B locus, and 13 for C locus) were used. HLA-DR typing was performed with B-lymphocytes by a two-stage microcytotoxicity method that was modified by longer incubation times[9] (serum for 60 minutes at 37° C, complement for 120 minutes at 15° to 25° C). There were also 34 alloantisera used to type for nine

Continued

(Pc) was obtained for each couple of particular antigens by means of the following equation: Pc = uncorrected p value × number of antigens examined for each locus. The relative risk (RR) for endometrial carcinoma to develop in a patient with a particular HLA antigen was calculated with the following equation: RR = A/a × b/B, where A is the numer of patients with the particular antigen, a is the number of patients without the antigen, B is the number of controls with the antigen, and b is the number of controls without the antigen.

Results

Incidence of HLA in endometrial carcinoma. As shown in Table I, six kinds of antigens, A2, A11, Aw24, A26, Aw31, and Aw33, in the HLA-A locus were found in cases of endometrial carcinoma. For the B locus, the 14 kinds of antigens shown in Table I were detected, but the incidence of any antigens in the A and B loci was not significantly different in endometrial carcinoma when compared with the Japanese control values. For the C locus, four kinds of antigens, Cw1, Cw3, Cw4, and Cw7, were detected (Table I). The incidence of Cw7 in endometrial carcinoma was 17.6%, significantly higher than in the control group (2.1%). The Pc was <0.006 and the RR was 9.9. The incidence of the other three antigens (besides Cw7) was not significantly different in endometrial carcinoma from that in the control group. For the DR locus, the nine kinds of antigens shown in Table I, DR1, DR2, DR3, DR4, DR5, DRw6, DR7, DRw8, and DRw9, were detected. Among these antigens, only DRw8 showed a significant increase (31.1%) in endometrial carcinoma, while it remained 12.6% in the control. The Pc was <0.009 and the RR was 3.1. All of the HLA typing data on each patient are presented in Table II.

Relationship between Cw7 or DRw8 and associated complications in endometrial carcinoma. As stated, it is well known that patients with endometrial carcinoma frequently have diabetes mellitus, hypertensive disease, or are obese. We decided therefore to investigate the relationship between the finding of Cw7 or DRw8 and the three frequent complications. Table III shows no correlation between the two factors.

Table III. Correlation between positive findings of Cw7 or DRw8 and three associated complications in endometrial carcinoma

Presence or absence of complications	Positive for Cw7 or DRw8	Negative for Cw7 or DRw8	Total
Present	14	28	42
Absent	16	16	32
Total	30	44	74

The χ^2 value was calculated from this 2 × 2 table. Result was not significant ($\chi^2 = 2.093$).

Table IV. Haplotype frequencies in patients with endometrial carcinoma

Haplotype	Patients with carcinoma	Controls
Aw24-DRw8	12/74 (16.2%)	
HF	0.0370	0.0168
D	−0.0265	−0.0056
A 2-DRw8	13/74 (17.6%)	
HF	0.0789	0.0205
D	0.0430	0.0050
A 2-Cw7	8/74 (10.8%)	
HF	0.0540	0.0007
D	0.0285	−0.0017

HF = Haplotype frequency; D = delta value.

Incidence of haplotypes of HLA. As shown in Table IV, the incidence of some haplotypes of HLA in the endometrial carcinoma group and the control group[11] was compared. The haplotype frequencies of Aw24-DRw8, A2-DRw8, and A2-Cw7 were 16.2%, 17.6%, and 10.8%, respectively. The delta values show negative disequilibrium between Aw24 and DRw8 and positive disequilibrium between A2 and DRw8 and also between A2 and Cw7. These haplotype values showed a stronger linkage disequilibrium than the control values.

A new classification of endometrial carcinoma based on HLA and associated complications. According to the results obtained, patients with endometrial carcinoma can be classified into four groups on the basis of HLA typing. The first type, group A, is defined as

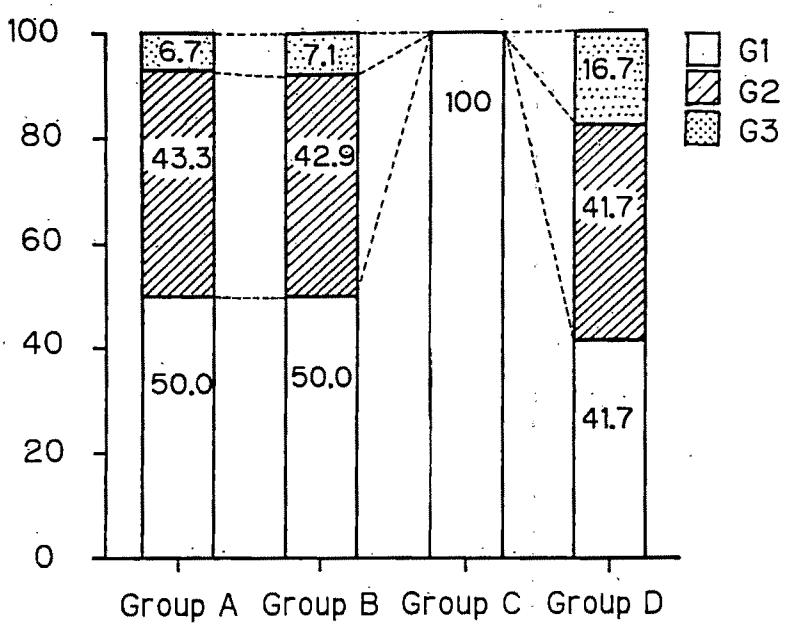

Fig. 1. Histologic differentiation of endometrial carcinoma in the four groups. G1 = Well-differentiated adenocarcinoma. G2 = Moderately differentiated adenocarcinoma. G3 = Poorly differentiated adenocarcinoma.

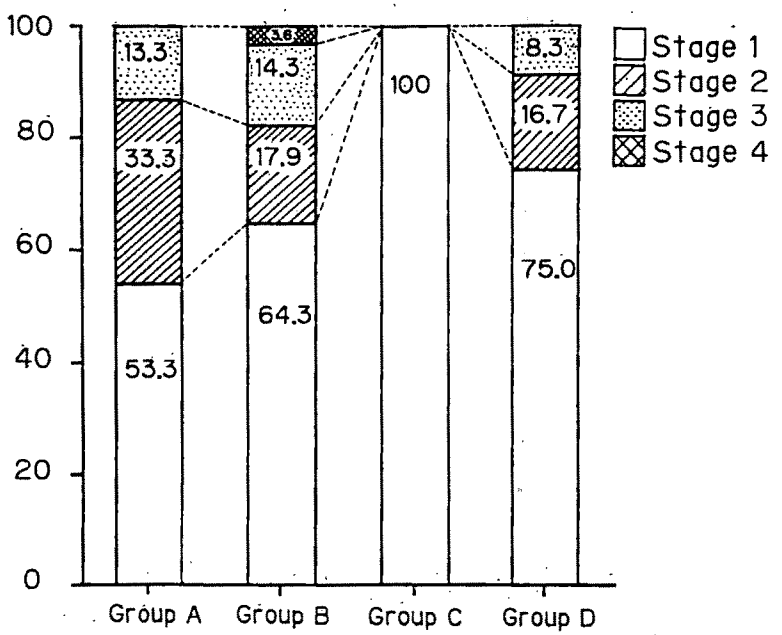

Fig. 2. Clinical stages of four groups of patients with endometrial carcinoma.

Table V. New classification of patients with endometrial carcinoma

Group	*Cw7 and/or DRw8*	*Associated complications (%)*	*DR5 (%)*	*No. of patients (n = 74)*	*Incidence (%)*
A	100	±	3.3	30	40.5
B	0	100	7.1	28	37.8
C	0	0	100	4	5.4
D	0	0	0	12	16.2

women with Cw7 and/or DRw8. As shown in Table V, 30 patients (40.5%) in the 74 cases of endometrial carcinoma belong to this group. The age range of this group was 29 to 73 years, with a median of 53. The endometrial histologic evaluation showed 50.0% G1, 43.3% G2, and 6.7% G3 (see Fig. 1). Clinical staging was as follows: Stage I, 53.3%; Stage II, 33.3%; Stage III, 13.3%; and Stage IV, 0% (Fig. 2).

Type B endometrial carcinoma is often associated with complications such as diabetes mellitus, obesity, or hypertensive disease, but not with Cw7 and DRw8 antigens. The HLA that was characteristic of this type was a high frequency of Cw3 (67.9%) or DR3 (17.9%). Twenty-eight patients (37.8%) of the endometrial carcinoma cases belong to this group (Table V). The age range was from 36 to 74 years, with a median of 57. The histologic types were 50.0% G1, 42.9% G2, and 7.1% G3 (Fig. 1). Clinical staging was 64.3% in Stage I, 17.9% in Stage II, 14.3% in Stage III, and 3.6% in Stage IV (Fig. 2).

Type C endometrial carcinoma is negative for Cw7 and DRw8, with no specific complications and positive HLA-DR5. The incidence of type C was 5.4% in 74 patients with endometrial carcinoma (Table V). The age range was from 45 to 62 years, with a median of 51. Histologic type in this group was 100% G1 (Fig. 1). Clinical staging was 100% Stage I (Fig. 2).

Type D endometrial carcinoma is defined as the non-A, non-B, and non-C type, that is, negative for Cw7, DR5, DRw8 and no particular complications. Twelve (16.2%) patients with endometrial carcinoma belong to this type (Table V). The age range was 31 to 72 years, with a median of 51. Histologic evaluation of this type showed 41.7% G1, 41.7% G2, and 16.7% G3 (Fig. 1). Clinical staging was as follows: Stage I, 75.0%; Stage II, 16.7%; Stage III, 8.3%; and Stage IV, 0% (Fig. 2).

Comment

In 1974 Simons et al.[12] reported that HLA-Bw46 had a substantial association with nasopharyngeal carcinoma; then the correlation between the HLA system and neoplastic diseases was reconsidered. Recently in the gynecologic field Sniecinski et al.[7] reported a significantly increased frequency of Aw31 in 21.0% of 38 patients with cervical carcinoma and of Aw23 in 17.6% of 17 patients with endometrial carcinoma. However, their report was based on only 17 cases of endometrial carcinoma, and there was a lack of investigation of the HLA-DR locus.

In this extensive study of the correlation between HLA antigens and endometrial carcinoma, including the examination of HLA-DR locus antigens, it was clearly demonstrated that the frequency of Cw7 and DRw8 was significantly increased in Japanese patients with endometrial carcinoma, while no associated antigens were detected in the HLA-A locus, including Aw23, and the B locus. These results, which demonstrated that no association was observed between the HLA-A and HLA-B loci and endometrial carcinoma, coincided with the reports by Takasugi et al.[13] and Terasaki et al.[14]

Since the correlation between Cw7 or DRw8 and the three complications was not demonstrated (Table I), types HLA-Cw7 and HLA-DRw8 seem to be new, constitutional, previously unreported risk factors involved in endometrial carcinogenesis.

A new classification of endometrial carcinoma based on both the HLA typing and the three associated complications was proposed according to the data obtained here.

We thank Dr. Kazuo Miyanaga, M.D., Department of Psychiatry, Gunma University School of Medicine, for his kind guidance with the HLA research methods.

An evaluation of squamous cell carcinoma antigen in patients with cervical squamous cell carcinoma

Elizabeth K. Senekjian, M.D.,* J. Maitland Young, Ph.D. Patricia A. Weiser, R.N., Cheryl Eck Spencer, M.S., Susan E. Magic, M.A., and Arthur L. Herbst, M.D.

Chicago, Illinois

In a prospective study, serum concentrations of squamous cell carcinoma antigen, a subfraction of tumor antigen (TA-4), were determined by radioimmunoassay from healthy donors, pregnant women, and subjects with various benign and malignant gynecologic diseases. Ninety-six percent of 99 healthy persons including all 52 female controls, the 15 pregnant patients, and all 23 subjects with benign gynecologic tumors, had squamous cell carcinoma antigen levels <2.0 ng/ml. Seven of 51 (14%) patients with cervical intraepithelial neoplasia and 16 of 24 (67%) patients with cervical squamous cell carcinoma had squamous cell carcinoma antigen levels >2.0 ng/ml. Declining and rising levels of squamous cell carcinoma antigen, which were determined sequentially in nine cases of cervical carcinoma that were associated with elevated pretreatment levels of squamous cell carcinoma antigen, correlated with regression and progression of the disease. Serial serum levels of squamous cell carcinoma antigen provide a noninvasive means of monitoring the effects of individual therapy in patients with cervical squamous cell carcinoma. (Am J Obstet Gynecol 1987;157:433-9.)

Key words: Squamous cell carcinoma antigen, cervical squamous cell carcinoma, tumor antigen (TA-4)

Tumor antigen (TA-4), a glycoprotein with a molecular weight of approximately 48 kilodaltons,[1] was isolated by Kato and Torigoe[2] from human cervical squamous cell carcinoma tissue. Elevated TA-4 levels, which were determined by radioimmunoassay, have been found in 55% of patients with cervical squamous cell carcinoma.[1] Furthermore, fluctuations in TA-4 values have been found to correspond with tumor progression and regression.[3]

Squamous cell carcinoma antigen, one of 14 subfractions of TA-4, has been purified from cervical squamous cell carcinoma metastatic to the liver by a modification of the method described by Kato and Torigoe.[2] Maruo et al.[4] recently reported significant elevations of antigen levels in Japanese patients with advanced cervical squamous cell carcinoma and normalization of levels after radical surgery or radiotherapy.

The management of patients with cervical carcinoma is hindered by limitations in clinical staging, accurate assessment of response to therapy, and early detection of tumor recurrence. A reliable, noninvasive method that overcomes these difficulties could allow for more timely alternative or additional therapy.

In this study squamous cell carcinoma antigen values were determined in the sera of control subjects, pregnant women, and persons with benign, premalignant, and malignant gynecologic tumors. Sequential levels of squamous cell carcinoma antigen were compared with the clinical course during therapy in a group of patients with cervical carcinoma. Similar studies were performed with CA 125 and carcinoembryonic antigen. The clinical use of the three markers in patients with cervical carcinoma was evaluated.

Material and methods

Sera were obtained from 99 apparently healthy persons, 52 women and 47 men, who ranged in age from 22 to 56 years (median, 29 years) and 15 pregnant women. Pretreatment serum samples were collected from 23 patients with benign gynecologic diseases, including paraovarian cyst (one), mucinous cystadenoma (one), Brenner tumor (one), pelvic inflammatory disease (four), endometrial hyperplasia (four), uterine leiomyomata (seven), and endometriosis (eight). Specimens were obtained prospectively from 51 patients with cervical intraepithelial neoplasia, 30 with cervical carcinoma, 11 with malignancies of the uterine corpus, four with ovarian adenocarcinoma, and eight with vaginal or vulvar squamous cell carcinoma. The serum specimens were stored at −20° C until assayed for squamous cell carcinoma antigen. Review of operative re-

From the Department of Obstetrics and Gynecology, Chicago Lying-In Hospital, University of Chicago, Pritzker School of Medicine, and Abbott Laboratories.

Table I. Pretreatment detection of serum squamous cell carcinoma antigen related to stage of cervical squamous cell carcinoma

Disease stage	*Total No. cases*	*SCC level >2.0 ng/ml*	*SCC range (ng/ml)*
Stage			
I	8	4	0.3-5.4
II	7	6	1.7-5.7
III	4	3	0.0-27.7
Recurrence	5	3	1.7-265.4
Total	24	16	0.0-265.4

SCC = Squamous cell carcinoma antigen.

Table II. Combination assay of squamous cell carcinoma antigen, carcinoembryonic antigen, and CA 125 in 30 patients with cervical carcinoma

	SCC + (%)	*SCC − (%)*
CEA +		
CA 125 +	10.0	3.3
CA 125 −	3.3	10.0
CEA −		
CA 125 +	6.7	0.0
CA 125 −	36.7	30.0

SCC = squamous cell carcinoma antigen; CEA = carcinoembryonic antigen.

ports, pathology reports, and examination of biopsy and/or surgical specimens confirmed diagnoses.

Pretreatment sera were available from 24 cases of newly diagnosed and six cases of recurrent cervical carcinoma. The median age of patients with cervical carcinoma was 45 years. Histologic examination revealed that 24 lesions were squamous cell carcinomas and six were adenosquamous carcinomas. Stage was assigned according to the classification of the International Federation of Gynecology and Obstetrics. Of the 24 newly diagnosed cases, 10 patients had Stage I disease, nine had Stage II, and five had Stage III. Multiple serum samples were collected from 16 patients with cervical carcinoma; 13 had cervical squamous cell carcinoma and three had cervical adenosquamous carcinoma. Tumor regression, stability, or progression was determined by changes in the dimensions of palpable masses or lesions detected by computed tomography or chest roentgenography. Tumor regression was defined as a 50% or greater reduction in the sum of the products of the two greatest perpendicular dimensions of each measurable lesion. Tumor progression was defined as a 50% or greater increase in the result of the calculation described above or the appearance of any new lesion. Stable disease was defined as tumor behavior that did not meet either of these criteria.

Serum determinations of squamous cell carcinoma antigen were performed in duplicate by means of the radioimmunoassay kit (Abbott SCC-RIA) available through Abbott Laboratories (North Chicago, Ill.). Briefly, assay tubes containing 100 μl of sample serum or standard squamous cell carcinoma antigen solution, 200 μl of iodine 125–labeled squamous cell carcinoma antigen, and 100 μl of anti–squamous cell carcinoma antigen serum were incubated at room temperature for 20 to 30 hours. Subsequently, 500 μl of second antibody (goat antirabbit γ-globulin) solution was added. The tubes were incubated at room temperature for 10 minutes and then centrifuged at 3000 rpm for 20 minutes at 4° C. The radioactivity in the pellet was counted.

Pretreatment serum values of CA 125 and carcinoembryonic antigen were determined for each of the 30 patients with cervical carcinoma. CA 125 levels were determined by means of the Abbott CA 125 radioimmunoassay procedure. This method uses OC125 monoclonal antibodies in a solid-phase immunoradiometric assay to measure the CA 125 antigen. A CA 125 value of 35 U/ml was considered the upper limit of the normal range. The carcinoembryonic antigen concentrations were determined with the Abbott CEA–enzyme immunoassay monoclonal kit. Carcinoembryonic antigen values greater than 3.0 and 5.0 ng/ml were considered abnormal in nonsmokers and smokers, respectively. The proportions of concentrations of pretreatment serum squamous cell carcinoma antigen, CA 125, and carcinoembryonic antigen above the normal range in patients with cervical carcinoma were compared by use of the z statistic for comparison of proportions in paired samples.[5]

Results

In 99 normal persons squamous cell carcinoma antigen levels ranged from <1.0 ng/ml to 3.2 ng/ml. Ninety-six percent of these healthy blood donors had squamous cell carcinoma antigen values <1.99 ng/ml, 97% had levels <2.04 ng/ml, and 98% had values ≤2.40 ng/ml. The mean squamous cell carcinoma antigen concentration (1.24 ng/ml) plus two standard deviations (0.82 ng/ml) was computed to be 2.06 ng/ml. Therefore, when both values (2.04 and 2.06 ng/ml) were taken into consideration, a serum squamous cell carcinoma antigen level of 2.0 ng/ml was designated to be the upper limit of the normal range. All 52 normal female subjects had squamous cell carcinoma antigen levels <2.0 ng/ml.

None of the 23 patients with benign disorders of the female genital tract had elevated serum squamous cell carcinoma antigen levels (range, 0 to 1.9 ng/ml). All 15 pregnant patients had serum squamous cell carcinoma

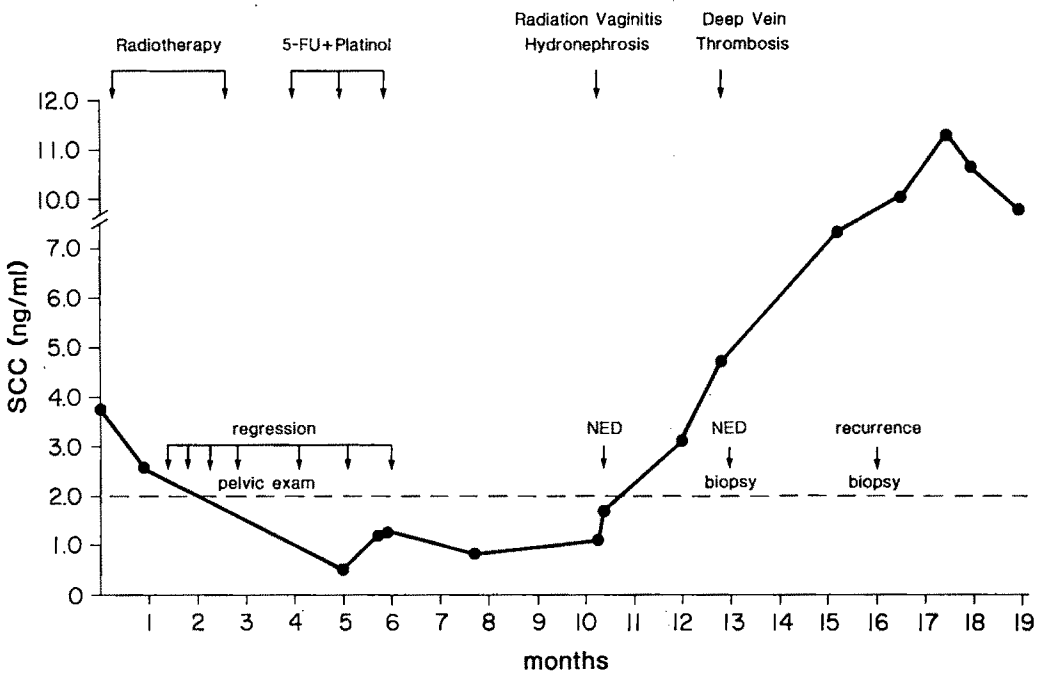

Fig. 1. Serial squamous cell carcinoma antigen *(SCC)* levels, response to therapy, and recurrence in a 30-year-old patient with a Stage IIA cervical squamous cell carcinoma. The *dotted line* denotes the upper limit for normal values of squamous cell carcinoma antigen, 2.0 ng/ml. *5FU* = 5-fluorouracil; *NED* = no evidence of disease.

antigen levels <2.0 ng/ml (range, 0 to 1.7 ng/ml). Elevated squamous cell carcinoma antigen levels were detected in seven of 51 patients with cervical intraepithelial neoplasia I, II, or III (range, 2.9 to 9.1 ng/ml). Six of the 23 patients with newly diagnosed gynecologic malignancies other than cervical carcinoma had elevated squamous cell carcinoma antigen levels (range, 2.1 to 66.6 ng/ml). Four of these latter six patients had squamous cell carcinomas of the vagina or vulva.

Among the 30 patients with newly diagnosed or recurrent cervical carcinoma, pretreatment squamous cell carcinoma antigen levels were ≤265.4 ng/ml. Seventeen (57%) of the 30 patients had elevated serum squamous cell carcinoma antigen levels. Only one of six patients with a cervical adenosquamous carcinoma had a squamous cell carcinoma antigen level in excess of 2.0 ng/ml; 16 (67%) of the 24 patients with cervical squamous cell carcinoma had elevated squamous cell carcinoma antigen levels. The distribution of serum squamous cell carcinoma antigen values by the stage of cervical squamous cell carcinoma is shown in Table I.

Of the eight cases of cervical squamous cell carcinoma with pretreatment squamous cell carcinoma antigen values <2.0 ng/ml, six had a small tumor burden. The diagnosis of Stage IB occult disease was made by cervical conization in three patients. One patient with Stage IB disease had a 2 cm cervical lesion and microscopic metastases in two pelvic nodes. In a patient with a Stage IIIB squamous carcinoma, the 2 cm cervical tumor was associated with a 0.5 cm metastasis involving the urethral meatus. One patient with tumor recurrence had two foci of microscopic disease in the cervix and vagina. In addition, four of seven patients with lesions 6 cm or greater in size had squamous cell carcinoma antigen values in excess of 5.0 ng/ml.

Pretreatment serum concentrations of CA 125 and carcinoembryonic antigen were determined for the 30 patients with cervical carcinoma. CA 125 values ranged from 5.2 to 446.5 U/ml and were elevated in six (20%) patients. Carcinoembryonic antigen levels ranged from 0.3 to 78.5 ng/ml and were elevated in eight (27%) subjects. Pretreatment squamous cell carcinoma antigen and carcinoembryonic antigen values were both elevated in four (13%) of the 30 patients (Table II). All three antigens were elevated in three (10%) patients and were within the normal range in nine (30%) patients. The proportion of patients with elevated pretreatment levels (57%) of squamous cell carcinoma antigen was significantly higher than the proportion having elevated carcinoembryonic antigen levels (27%) or CA 125 levels (20%) ($p < 0.05$). The number of patients having elevated carcinoembryonic antigen levels compared with elevated CA 125 levels was not significantly different.

Serial serum samples were obtained from 16 patients

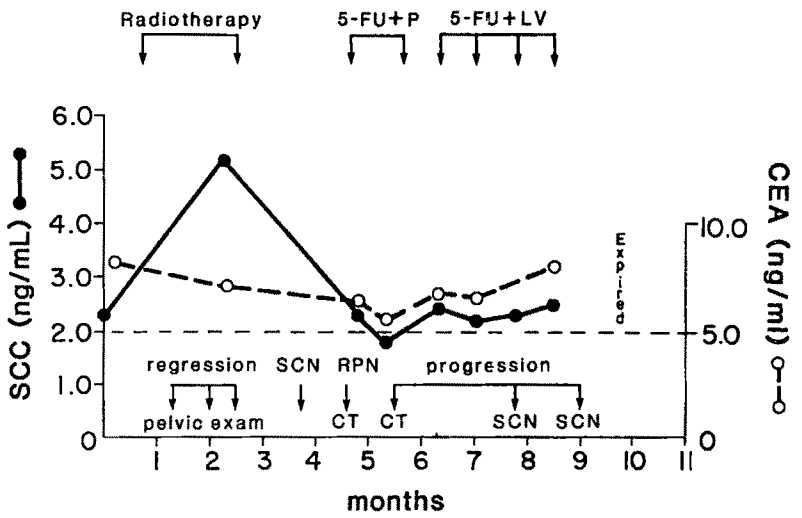

Fig. 2. Serum squamous cell carcinoma antigen values *(solid circles)* and carcinoembryonic antigen values *(open circles)* during therapy in a 51-year-old patient with a Stage IIIB cervical squamous cell carcinoma. The *dotted line* represents the upper limit for normal values of squamous cell carcinoma antigen (2.0 ng/ml) and carcinoembryonic antigen (5.0 ng/ml, smoker). *P* = Platinol; *LV* = leucovorin; *SCN* = supraclavicular adenopathy; *RPN* = retroperitoneal adenopathy, *CT* = computed tomography. See Fig. 1.

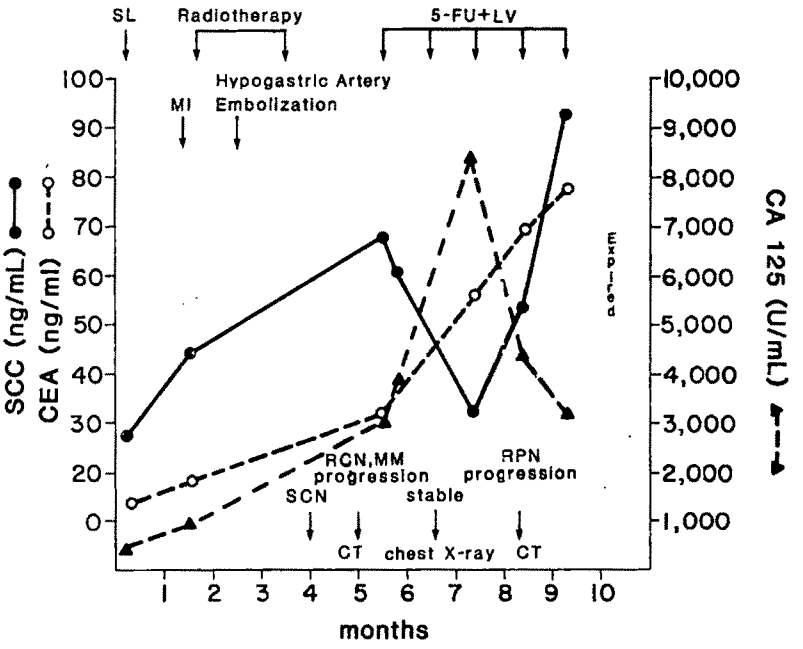

Fig. 3. Serum squamous cell carcinoma antigen concentrations *(solid circles)*, carcinoembryonic antigen levels *(open circles)*, and CA 125 levels *(solid triangles)* in a 42-year-old patient with a Stage IIIB cervical squamous cell carcinoma during irradiation and chemotherapy. *SL* = Staging laparotomy; *MI* = myocardial infarction; *RCN* = retrocrural adenopathy; *MM* = mediastinal mass; *CEA* = carcinoembryonic antigen. See Figs. 2 and 3.

with cervical carcinoma. Three to 11 specimens were available for each patient over a 2- to 15-month period. Pretreatment squamous cell carcinoma antigen levels were <2.0 ng/ml in seven of the 16 patients; antigen values remained within the normal range in four, rose transiently during radiotherapy in two, and increased to 4.9 ng/ml in one case coincident with lung and supraclavicular node metastases.

Pretreatment squamous cell carcinoma antigen values were elevated in nine of the 16 patients from whom

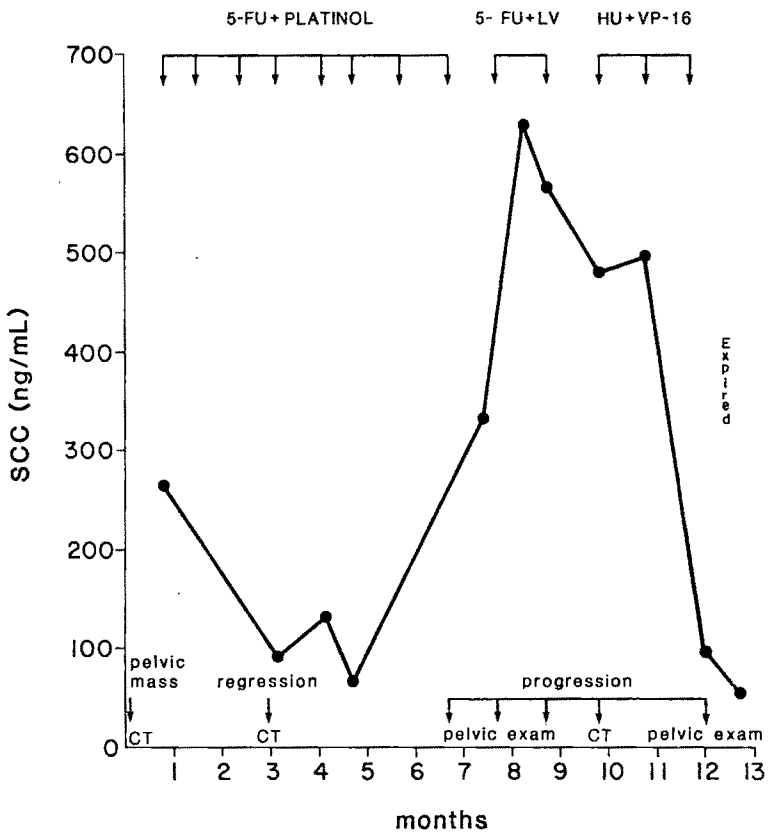

Fig. 4. Serial squamous cell carcinoma antigen levels during chemotherapy in a 32-year-old patient with recurrent cervical squamous carcinoma. *HU* = Hydroxyurea. See Figs. 1 through 3.

serial serum samples were collected. Eight patients had cervical squamous cell carcinoma and one had adenosquamous carcinoma. Two patients, one with a Stage IB and the other with a IIA lesion, have completed whole-pelvis external irradiation. Decline in squamous cell carcinoma antigen levels to <2.0 ng/ml occurred in both cases, at 11 and 27 Gy (1 Gy is equal to 100 rad), in association with regression of the visible and palpable tumor.

Two patients with Stage IB and IIIA lesions remain clinically free of disease 10 and 15 months after the initial diagnosis. Squamous cell carcinoma antigen levels fell to <2.0 ng/ml after therapy and remained within the normal limits. In contrast, Fig. 1 shows re-elevation of squamous cell carcinoma antigen values in one patient 12 months after the diagnosis of a Stage IIA cervical squamous cell carcinoma; however, recurrence could not be confirmed until 4 months after the elevated squamous cell carcinoma antigen level.

Two subjects received radiation therapy for bulky (diameter >6 cm) Stage IIB and IIIB cervical tumors (Figs. 2 and 3). Metastatic disease involving the supraclavicular nodes was confirmed 4 months after the initial diagnosis in both patients. With the administration of chemotherapy, squamous cell carcinoma antigen values decreased transiently in both patients and fell to within the normal limits in one. Squamous cell carcinoma antigen values stabilized to levels approaching 2.5 ng/ml in one patient and rose to a maximum of 92.2 ng/ml in the other. Both patients died of disease 10 months after the initial diagnosis.

In two patients with recurrent cervical carcinoma, pelvic masses were detected at 19 and 34 months after radiotherapy for Stage IIB and IB lesions (Figs. 4 and 5). In one case, serum squamous cell carcinoma antigen values fell from 265.4 ng/ml to 90.6 ng/ml (a level 45-fold greater than the reference value) after three courses of chemotherapy, coincident with tumor regression (Fig. 4). Squamous cell carcinoma antigen values increased and then fell to 51.4 mg/ml (a level 26-fold greater than the reference value) in association with progression of disease. In the second case, squamous cell carcinoma antigen levels fell to <2.0 ng/ml after four courses of chemotherapy (Fig. 5) in association with stabilization of disease. Elevated squamous cell carcinoma antigen levels were observed 5 months before evidence of progression.

Declining (Figs. 1 and 4) and rising (Figs. 2

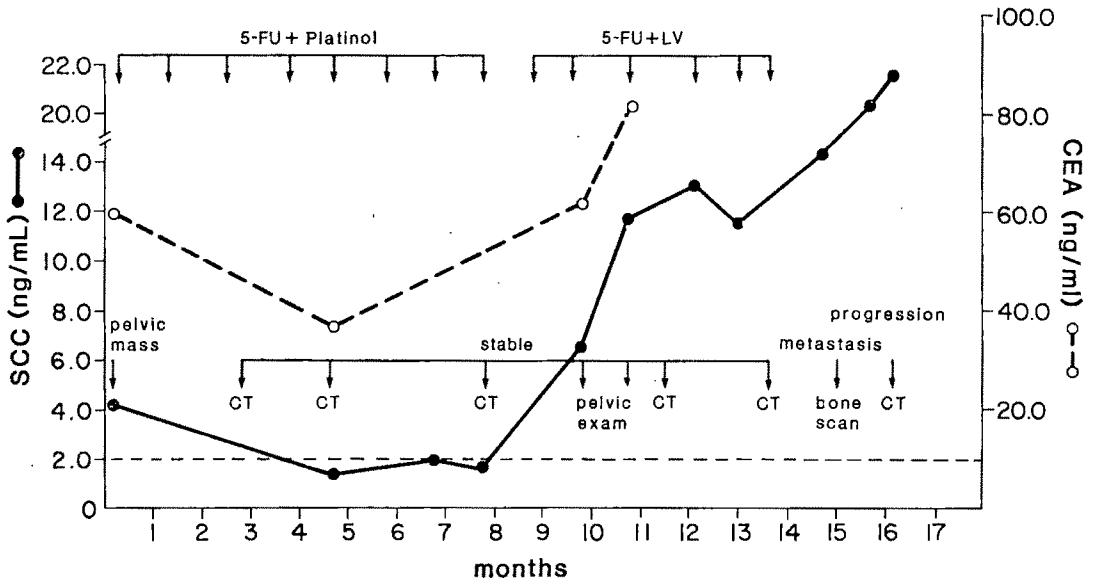

Fig. 5. Serum squamous cell carcinoma antigen concentrations *(solid circles)* and carcinoembryonic antigen *(open circles)* during chemotherapy in a 42-year-old patient with recurrent cervical adenosquamous carcinoma. The chemotherapy regimen was modified because of neurotoxicity. See Figs. 1 through 4.

through 5) squamous cell carcinoma antigen levels, respectively, corresponded with disease regression and progression. Elevated squamous cell carcinoma antigen levels anteceded clinical evidence of disease progression by 5 months in one case (Fig. 5) and antedated detectable recurrence by 4 months in another (Fig. 1). In one patient, three CA 125 values varied in parallel with paired squamous cell carcinoma antigen levels whereas the two antigens fluctuated in opposite directions for four values (Fig. 3). All but two of 17 paired carcinoembryonic antigen and squamous cell carcinoma antigen levels (Figs. 2, 3, and 5) varied in the same direction.

Comment

Clinical trials by Japanese investigators have demonstrated good agreement between serum TA-4 values and the extent,[1,6] prognosis,[7] and progression[3] of cervical squamous cell carcinoma. Normalization of TA-4 levels was observed to occur within 7 to 14 days after radical hysterectomy.[1,3] Furthermore, elevated TA-4 values preceded clinical evidence of recurrent disease by a mean of 3.6 months in 11 of 15 patients.[8]

Recently, Maruo et al.[4] reported the usefulness of measuring the subfraction of TA-4 in patients with cervical squamous cell carcinoma. In the Japanese population, 52% of 73 patients had elevated squamous cell carcinoma antigen levels (>2.5 ng/ml in the study by Maruo et al.[4]). A greater proportion of patients with advanced disease had elevated squamous cell carcinoma antigen levels relative to patients with early disease. Only 16% of Stage I versus 83% of Stage III tumors were associated with squamous cell carcinoma antigen values >2.5 ng/ml. Higher mean values of the antigen were reported in more advanced stage lesions. In addition, squamous cell carcinoma antigen levels fell below the reference value within 72 hours of radical hysterectomy in 15 of 16 patients, whereas in seven of eight subjects receiving radiotherapy, a transient rise in levels during the initial 20 Gy was followed by a decline to normal limits after 40 to 60 Gy.[4]

In this study, all 52 female donors, all 15 pregnant patients, and the 23 subjects with benign gynecologic disease had serum squamous cell carcinoma antigen levels <2.0 ng/ml. Therefore, consistently low levels of squamous cell carcinoma antigen were found in sera from healthy women and in patients with nonmalignant gynecologic tumors. Elevated pretreatment levels of squamous cell carcinoma antigen (>2.0 ng/ml in this study) were observed in 14% of 51 patients with cervical intraepithelial neoplasia and 67% of 24 patients with cervical squamous cell carcinoma. Squamous cell carcinoma antigen levels exceeded 2.5 ng/ml in 12 (50%) subjects with cervical squamous cell carcinoma. These findings are consistent with earlier studies by Japanese investigators. However, the test is not suitable for screening persons for invasive cervical carcinoma, since elevated levels occur in cases of cervical intraepithelial neoplasia and values <2.0 ng/ml are seen in subjects with cervical carcinoma.

Elevated squamous cell carcinoma antigen values were detected in four of eight patients with vaginal or vulvar squamous cell carcinoma. Additional investigation may demonstrate that the assay is useful in monitoring the clinical course of patients with these malignancies.

Among the 30 patients with cervical carcinoma, pretreatment squamous cell carcinoma antigen levels were elevated more frequently than were carcinoembryonic antigen levels (57% versus 27%); however, elevated carcinoembryonic antigen values were associated with normal squamous cell carcinoma antigen levels in 13% of these cases of cervical carcinoma. Therefore, carcinoembryonic antigen in conjunction with squamous cell carcinoma antigen determinations may be of value in monitoring patients with cervical carcinoma. Only 20% of patients had elevated CA 125 values, and in all patients elevated levels were accompanied by elevated carcinoembryonic antigen and/or squamous cell carcinoma antigen levels. No benefit was demonstrated for the assay of CA 125 in cases of cervical carcinoma.

In general, good agreement was found between squamous cell carcinoma antigen values and regression, progression, and recurrence of cervical carcinoma. Rising squamous cell carcinoma antigen values were associated with tumor progression (Figs. 2 through 5) or recurrence (Fig. 1) and preceded clinical evidence in two patients by 4 and 5 months (Figs. 1 and 5). Persistently elevated levels of serum squamous cell carcinoma antigen have been consistently associated with limited survival. Declining squamous cell carcinoma antigen levels were observed in six of nine cases of cervical cancer in association with objective tumor regression (Figs. 1, 2, and 4). However, declining values may also accompany disease progression or stabilization (Figs. 2 through 5). Furthermore, a fall in squamous cell carcinoma antigen values to <2.0 ng/ml may not always coincide with a tumor-free state (Figs. 2 and 5).

Elevated squamous cell carcinoma antigen values warrant thorough evaluation to delineate the presence and/or extent of disease. Rising squamous cell carcinoma antigen levels suggest the need for modification in the future course of therapy, namely, radical surgery and/or chemoradiotherapy for cure and/or discontinuation of ineffective chemotherapeutic regimens to avoid undue toxicity and permit the use of other agents for palliation.

Based on the few cases studied, rising levels of serum squamous cell carcinoma antigen appear to be predictive of progressive or recurrent disease while declining antigen values may coexist with regression, progression, or stabilization of tumor. Despite documentation of a downward trend in squamous cell carcinoma antigen levels, a highly elevated absolute value, several times greater than the reference value of 2.0 ng/ml, suggests the presence of a significant tumor burden. Squamous cell carcinoma levels within the normal range do not exclude the presence of tumor.

Although data from a larger number of cases of cervical carcinoma are necessary to establish guidelines for interpreting significant changes in serial levels of serum squamous cell carcinoma antigen, serum squamous cell carcinoma antigen determinations provide a noninvasive means of monitoring individual therapy in patients with cervical squamous cell carcinoma. Serum squamous cell carcinoma antigen concentrations obtained at intervals during initial therapy and thereafter may be of value in detecting persistent, progressive, or recurrent cervical carcinoma.

Neonatal auditory acuity following in utero vibratory acoustic stimulation

G. Ohel, M.D., E. Horowitz, M.D., N. Linder, M.D., and H. Sohmer, M.D.
Jerusalem, Israel

The fetal heart rate response to externally applied vibratory acoustic stimulation is currently being evaluated as a test of fetal well-being. We have examined the safety of this procedure by subsequent testing of the auditory nerve and brain stem evoked responses in the neonates. The results demonstrated no differences in auditory acuity when control infants were compared with infants previously exposed to antenatal vibratory acoustic stimulation. (AM J OBSTET GYNECOL 1987;157:440-1.)

Key words: Vibratory acoustic stimulation, neonatal auditory functioning

The fetal heart rate (FHR) response to externally applied vibratory acoustic stimulation and its possible relevance to fetal well-being are currently being reevaluated.[1,2] The safety of antenatal vibratory acoustic stimulation in regard to subsequent neonatal auditory functioning has not been assessed carefully in the past. With this in mind, we have evaluated the auditory nerve and brain stem responses of neonates following their in utero exposure to vibratory acoustic stimulation.

The recording of auditory nerve and brain stem evoked responses to auditory stimuli is being used for the diagnosis of conditions such as hearing loss and neurological disorders at all ages, including neonates.[3] Details of the method were described elsewhere.[3] Briefly, the auditory stimuli were 10-second clicks, generated in earphones, from 80 dB in intensity above the threshold of the normal adult population down to 40 dB.

The responses were recorded as the potential difference between an earlobe and a scalp electrode. The electrical activity was filtered (bandpass 200 to 2000 Hz), amplified, and averaged by an average response computer (Microshev 2000). The auditory evoked potentials that are thus processed can determine the electrical response of the auditory system from the cochlea to the rostral brain stem. In the present study, we have evaluated several indices of normalcy from such recordings: a screening procedure for threshold, taken as the presence of replicable auditory nerve and brain stem evoked responses at 40 to 50 dB and latency measures of the auditory nerve and brain stem evoked responses to 80 dB clicks, including the latency of the first wave that is generated in the auditory nerve and the brain stem transmission time, which is a measure of the time interval between the auditory nerve response and a response from a more rostral region of the brain stem.[3]

Material and methods

Forty healthy neonates were examined 1 to 2 days after normal term deliveries. Twenty of these had been exposed to vibratory acoustic stimulation in labor. In the remaining cases, no such stimulation was received and these infants served as controls. For the stimulation, we have used a vibratory acoustic noise source, of a type used in some current clinical studies (Model 5B Electrolarynx, Western Electronic; audible sound 750 to 1000 Hz, output intensity 110 dB, vibrations between 110 and 200 Hz).[1,2] Three stimulations of 5 seconds' duration each were applied to the maternal abdomen overlying the fetal head, at the time of active labor. The FHR acceleration response was noted after each stimulation.

Results

The results of the neonatal auditory and brain stem evoked reponse studies are summarized in Table I. There were no differences in the first-wave latency times and the brain stem transmission times when the study and control neonates were compared (t test). In addition, both groups had similar auditory nerve and brain stem evoked response thresholds, which were never greater than 50 dB.

Comment

The presumed safety of fetal vibratory acoustic stimulation, which utilizes sound intensities of 110 dB, seems justified when the relatively high intrauterine background noise of about 70 dB and the attenuation of extramaternal sounds are considered. The present study, by use of an objective and sensitive test method, demonstrates no untoward effects on the auditory

Table I. Latency of auditory nerve response and brain stem transmission time in neonates after labor with and without vibratory acoustic stimulation

Breakage of a fetal scalp blade with retention of fragments in the infant's scalp

Phillip Nieburg, M.D., M.P.H., and Steven J. Gross, M.D.
Boston, Massachusetts, and Atlanta, Georgia

A term infant underwent scalp blood sampling just prior to delivery because of fetal tachycardia. Afterward, a portion of the scalp blade tip was missing and was noted in two fragments on x-ray film. Because of concern about the difficulty of removal, the fragments were left in situ. The infant progressed well. (Am J Obstet Gynecol 1987;157:441-2.)

Key words: Fetal scalp blade, retained fragments, management

As fetal scalp blood sampling has come into wider use for the assessment of fetal status during labor, complications of the procedure have been only infrequently reported. We would like to report a case of breakage of a fetal scalp blade with retention of the blade fragments in the infant's scalp.

Case report

A 3060 gm male infant was born to a 17-year-old, gravida 1, para 0 woman after an uncomplicated 38-week pregnancy. Labor lasted approximately 18 hours. Because of an apparent fetal tachycardia (160 to 190 bpm) noted after 12 hours of labor, membranes were ruptured and fetal blood for pH measurement was obtained by means of a scalp pH blade. At the termination of this procedure, a portion of the blade tip was noted to be missing.

Remainder of the 18-hour labor and delivery was uncomplicated. Fetal pH was 7.31. Apgar scores were 8 and 9 at 1 and 5 minutes, respectively, after a low-forceps vaginal delivery. Examination of the newborn infant was unremarkable. The scalp blood sampling site, although scabbed and easily visible, was not swollen or inflamed.

X-ray examination of the infant's skull, performed because of concern about the fractured blade, disclosed two radiopaque objects, each about 2 mm in longest dimension, lying over the right parietal bone, approximately 3 cm lateral to the sagittal suture (Fig. 1). One

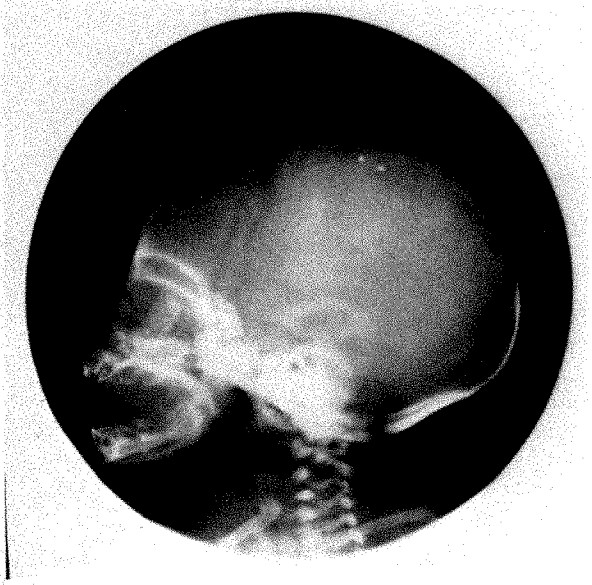

Fig. 1. X-ray film of infant's skull demonstrating two radiopaque blade fragments.

was 2.5 cm and the other 3 cm posterior to the coronal suture. A surgical consultant indicated that removal of these objects would be difficult and that, in view of their apparently inert nature, no indication for their removal existed. The parents were so advised.

The infant's subsequent hospital course was uneventful; he was discharged with his mother on the fourth postpartum day. He was progressing well on follow-up at 3 months of age.

Comment

Although recommendations have previously been made for careful scalp blade inspection after use,[1] we are unaware of previous published reports of retained blade fragments.

However, retention of spiral scalp electrode fragments in the scalp was reported by Thoulon and Gonnet.[2] A missing spiral electrode fragment was localized by x-ray film and removed with the infant under local anesthesia. Follow-up was uncomplicated. Lauritsen[3] reported a recurrent scalp abscess in a child admitted at 3½ months of age. An 8 mm scalp electrode fragment, not previously noted to be missing, was removed at the time of abscess incision and drainage.

An approach to the problem of retained blade fragment(s) other than that described above has been the gentle probing of the incision site with a small mosquito clamp to which has been applied a small magnet (such as that used to mix blood in a capillary tube). The magnetized probe may attract the metal fragment, which can then be gently lifted out of the scalp (Paul R, personal communication).

Experience with our case confirms that careful inspection of both fetal scalp blades and spiral electrodes is important after their use. In addition, evaluation of young infants with scalp abscesses should include x-ray examination for blade or electrode fragments if fetal scalp blood sampling or scalp electrode monitoring has occurred.

Review of causes of perinatal mortality in a regional perinatal center, 1980 to 1984

Arne Ohlsson, M.D., Andrew T. Shennan, M.B., and Toby H. Rose, M.D.
Toronto, Ontario, Canada

During 1980 to 1984, 279 deaths occurred among 15,306 births in a regional perinatal unit. Survival to discharge corrected for lethal malformations was 81% or better in infants with a birth weight above 749 gm. Congenital malformations (23.2%), infections (21.3%), asphyxia (19.8%), and hyaline membrane disease (11%) caused most perinatal deaths. (AM J OBSTET GYNECOL 1987;157:443-5.)

Key words: Perinatal mortality review, congenital malformations, infections, neutropenia, neonate

The purpose of this study was to review all perinatal deaths in a regional perinatal unit to indicate areas for improvements and research.

Material and methods

The Perinatal Unit at Women's College Hospital, Toronto, Ontario, Canada, serves both as a community hospital and as a level III perinatal facility for the Central East Region of Ontario, which has approximately 55,000 deliveries per year. Details of the perinatal management in the unit have been published previously.[1]

All perinatal deaths occurring in 15,306 in-hospital births of >20 weeks' gestation during 1980 to 1984 were reviewed. The cause of death was coded according to the International Classification of Diseases (ICD), 9th edition. The ICD code "extreme immaturity" was used only for appropriately grown neonates with a birth weight <600 gm, who died of a condition directly related to immaturity. "Definite infection" was defined as a clinical picture compatible with severe infection and growth of bacteria or virus in blood, cerebrospinal fluid, or tissue material at autopsy or a microscopic diagnosis of pneumonia. "Probable infection" was defined as a clinical picture compatible with serious infection, bacterial colonization, and neutropenia (mature neutrophils <1300/mm³) or leukocytosis (leukocytes >30,000/mm³) and no other obvious causes of death. The occurrence of air leaks (pneumothorax, pneumomediastinum, pneumopericardium) and cardiac dysrythmias were noted in all neonatal deaths.

infant deaths and the survival rates are shown in Table I. The first-week survival rate increased from 15.6% below 600 gm to 71.4% in the 600 to 749 gm weight group. The distribution of early neonatal deaths that possibly could have been avoided according to gestational age is shown in Fig. 1. Multiple birth was associated with 13.3% of all deaths. The main causes of perinatal deaths and infant deaths are shown in Table II. The autopsy rate was 70%. Thirty-eight percent of the stillbirths occurred in hospitalized mothers. Air leaks occurred in 25.3% of the neonatal deaths. Renal failure causing hyperkalemia and cardiac tachydysrythmias occurred in 12.4% of early neonatal deaths <1000 gm. Early neonatal deaths from infections were associated with premature rupture of the membranes for >24 hours in 39% and infection in 67% of the mothers. Seventy-seven percent of the early neonatal deaths that were due to a definite infection involved neutropenia. Gram-negative bacteria were most commonly isolated (34%).

Comment

Prevention of preterm birth and low birth weight remains the major challenge in reproductive medicine today as mortality is closely linked to immaturity and low birth weight (Table I, Fig. 1). Multiple births carry a high risk of perinatal death. Events such as intraventricular hemorrhage, air leaks, and dysrythmias secondary to hyperkalemia often precede death in critically sick neonates.

The major cause of perinatal death was congenital malformation (23.2%). Many of these anomalies were detected antenatally, but very few conditions were potentially amenable to fetal operations. Elective abortion after early antenatal diagnosis is presently the only available approach to decrease this major cause of mor-

tality. Routine use of ultrasonography at 17 and 33 weeks' gestation in all pregnant women[2] detects not only congenital anomalies but also other conditions associated with perinatal death such as multiple births and growth retardation.

It has been argued that with the advent of intensive care, perinatal mortality has been improved by moving inevitable deaths into the infant age group. In this study only 6% of the deaths occurred between 28 days of life and discharge to home, and the survival rates to discharge were minimally affected by late neonatal deaths or infant deaths (Table I). Given a birth weight of >749 gm and no congenital malformations the chance of survival to discharge to home was 81% or better.

The second most common cause of perinatal death was infection (21.3%). Neutropenia, known to be associated with poor outcome, occurred in 77% of the early neonatal deaths that were due to a definite infection. The incidence of maternal infection that was undetected prior to delivery was high in this group. Tests used so far to detect infectious morbidity in mothers with premature rupture of the membranes lack both sensitivity and specificity.

Hyaline membrane disease, infection, and asphyxia were the main, possibly preventable deaths (Fig. 1). Only one neonate born after 28 weeks' gestation died of hyaline membrane disease, but 10 died of infection. However, hyaline membrane disease remained the major cause of possibly preventable neonatal death at gestational ages below this (Fig. 1). Hyaline membrane disease also caused late neonatal deaths and was the initial diagnosis in seven infant deaths that were due to bronchopulmonary dysplasia and in one infant death due to tracheal stenosis. Bronchopulmonary dysplasia was the major cause of possibly preventable infant deaths.

This study represents a selected high-risk population of pregnant mothers admitted to a regional perinatal unit and should be complemented by an audit of all perinatal deaths in the geographic region served by the unit. Such an audit should also consider sociodemographic factors influencing pregnancy outcome. Randomized controlled studies are needed to determine the effectiveness of new interventions to prevent and/or treat preterm delivery, premature rupture of the membranes, low birth weight, maternal-fetal bacterial infections, hyaline membrane disease, and hyperkalemia.

Mexiletine use in pregnancy and lactation

Holly E. Lownes, M.D., and Timothy J. Ives, Pharm.D.
Chapel Hill, North Carolina

Treatment of arrhythmias during pregnancy is complicated by insufficient information on the effects of the drug on the fetus or possible alterations of the drug's pharmacodynamics in the mother. The use of mexiletine, a newly introduced antiarrhythmic agent, during the entire course of pregnancy and subsequent lactation is presented. (Am J Obstet Gynecol 1987;157:446-7.)

Key words: Mexiletine, pregnancy, lactation, ventricular tachycardia

The fact that women continue to take medications during pregnancy and lactation is not a new observation; however, data on such drug use are limited for most agents. Paucity of such information, particularly for newly marketed drugs, may severely limit the therapeutic prerogatives of a physician when caring for a pregnant patient. Use during pregnancy of mexiletine (Mexitil, Boehringer Ingelheim, Ridgefield, Connecticut), a recently introduced type Ib antiarrhythmic agent, has been reported only twice in the medical literature.[1,2] In neither case, however, was mexiletine initiated prior to conception. We report on a patient who received mexiletine during the entire pregnancy and subsequent breast-feeding.

Case report

A 26-year-old woman, gravida 1, paro 0, presented at 13.5 weeks' gestation for prenatal care. Her past medical history was significant for mitral valve prolapse, first diagnosed at age 13, and ventricular tachycardia with multifocal ectopic beats. Control was poor over the years with various combinations of quinidine, phenytoin, propranolol, disopyramide, and flecainide. At age 24, she was begun on a regimen of mexiletine (200 mg three times per day) and atenolol (50 mg per day). The mexiletine dose was subsequently titrated to 250 mg three times per day; she remained on a regimen of that and atenolol, 50 mg per day, throughout her conception, pregnancy, and postnatal course.

Her prenatal course was complicated by two episodes of *Escherichia coli* urinary tract infections, both of which responded to ampicillin. There was a question of possible intrauterine growth retardation at 34 weeks' gestation, but this was not validated by two consecutive ultrasound studies (there was symmetric body-head growth consistent with 33 weeks at 35 weeks 4 days by dates). However, the fetus was thought to be small for gestational age. During her pregnancy, there was no apparent change in her dysrhythmia. A 24-hour Holter monitoring at 15 weeks' gestation showed two four-beat runs of ventricular tachycardia (145 to 225 bpm) with occasional to frequent multiform ventricular premature beats, including rare triplets, occasional to frequent pairs, and some interpolated, intermittent bigeminy and trigeminy. Furthermore, Holter monitoring revealed baseline ectopy and one four-beat run of ventricular tachycardia (110 bpm) at 24 weeks' gestation and one eight-beat burst of ventricular tachycardia (135 to 180 bpm) at 27 weeks. She continued to work until 35 weeks' gestation. Throughout the course of pregnancy, the patient experienced no adverse effects that were thought to be attributable to mexiletine.

At 39 weeks, she had premature rupture of the membranes. With epidural anesthesia and Pitocin induction, she had an uneventful 8.5-hour labor (6-hour first stage, 2.5-hour second stage) and vaginal delivery (no forceps required) of a healthy male infant with a birth weight of 2600 gm and Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. Maternal cardiac monitoring during labor and delivery revealed the baseline and/or decreased ectopy. Serum mexiletine levels of the mother on admission and the child 9 hours post partum were <0.2 and 0.4 μg/ml, respectively (normal therapeutic range = 0.75 to 2.0 μg/ml).

The baby had a normal newborn course with heart rates of 120 to 160 bpm. At 17 days of life, he weighed 2155 gm and was feeding on breast milk only. It was felt that this was a case of failure to feed. With maternal education and formula supplementation, he regained his weight and had an acceptable growth curve. At 3 months of age, breast-feeding was discontinued. At 8 months, he was evaluated for seizure-like episodes. He had a normal neurological examination and a negative eletroencephalogram, but was found to have gastroesophageal reflux, which was diagnosed by an overnight pH probe and responded to corrective measures. He is currently 10 months old and in good health, with age-appropriate development.

Comment

In most cases where atenolol has been used during pregnancy and the puerperium, the effects on the fetus, labor, and the neonate are minimal, although fetal bradycardia has been reported. Unlike atenolol, mexiletine is lipid soluble and freely crosses the placenta. Mexiletine is also excreted into breast milk with a mean breast milk/plasma ratio of 1.45,[2] indicating a higher drug concentration in milk than in the maternal plasma. Investigators[1] consider this concentration to be insufficient for measurement in the neonatal serum, but such was not the case in this patient. Although the American Academy of Pediatrics considers atenolol acceptable for use during breast-feeding, no such recommendation has as yet been made for mexiletine. Alternatives to breast-feeding should be considered while the mother is receiving mexiletine.

In our single experience, mexiletine did not appear to cause any long-term adverse consequences, but with the appearance of several disturbing situations (suboptimal growth during the first weeks post partum or failure to feed) clinicians should continue to exercise extreme caution with its use during pregnancy and lactation.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Vasopressin-induced bradycardia in fetal and adult sheep is not dependent on an increase in blood pressure

Margaret A. Harper, M.D., and James C. Rose, Ph.D.
Winston-Salem, North Carolina

Other investigators have reported that intravenous infusion of synthetic arginine vasopressin into fetal lambs increases mean arterial pressure and decreases heart rate. To determine if the bradycardia produced by arginine vasopressin is a reflex response to the increase in blood pressure, we studied the effect of arginine vasopressin infusion on heart rate with and without blocking the increase in blood pressure. We performed 34 experiments in 12 chronically cannulated fetal lambs between 103 and 137 days' gestation. All animals had normal blood gas and pH values. Infusion of arginine vasopressin increased mean arterial pressure 10.1 ± 1.1 mm Hg and decreased heart rate 50 ± 8 bpm. Fetal heart rate decreased similarly when arginine vasopressin was infused and the hypertensive response was blocked with nitroprusside or a selective vasoconstrictor antagonist [1-(β-mercapto-β,β-cyclopentamethylene proprionic acid) 2-(0-methyl) tyrosine] arginine vasopressin. For comparison we also studied five adult nonpregnant ewes. Bradycardia was observed in the adults after infusion of arginine vasopressin alone and when the hypertensive response was blocked with the vasoconstrictor antagonist. We conclude that arginine vasopressin infusion causes a fall in heart rate independent of any increase in blood pressure in both the fetal lamb and the adult sheep. (Am J Obstet Gynecol 1987;157:448-53.)

Key words: Vasopressin, baroreceptor response, fetal lamb

Plasma concentrations of arginine vasopressin in sheep fetuses have been shown to be elevated in association with hypoxia, hemorrhage, and hypotension.[1-5] Intravenous infusion of arginine vasopressin into the sheep fetus causes an increase in blood pressure, a decrease in heart rate, and a redistribution of blood flow.[6-8] For these reasons, a role for arginine vasopressin in the fetal cardiovascular response to intrauterine stress has been suggested. The increase in blood pressure is due at least in part to direct peripheral vasoconstriction.[9] The mechanism of bradycardia has not been completely elucidated. Arginine vasopressin–induced bradycardia has been attributed to a direct effect of the peptide on the heart, a reflex response to the increase in blood pressure mediated by activation of the vagal efferents, inhibition of the cardioaccelerator mechanism, or a direct central effect on the cardioregulatory neurons.[10] The effect of an intravenous infusion of arginine vasopressin on heart rate while the pressor response is controlled has not previously been reported in the fetus. The present study was designed to determine what role, if any, increased blood pressure has in arginine vasopressin–induced bradycardia in the fetal lamb and adult sheep.

Material and methods

Animal preparation. We studied 12 chronically cannulated fetal lambs between 103 and 137 days' gestation and five adult nonpregnant ewes. Details of surgical procedures and animal maintenance have been described.[5] Briefly, ewes were deprived of food for 48 hours before operation. At operation the animals were anesthetized with ketamine and phenobarbital. In the pregnant ewes the uterus was exposed through a midline abdominal incision, the hind limbs of the fetus were delivered through a small uterine incision, and polyvinyl catheters were placed in a peripheral artery and vein and advanced into the aorta and inferior vena cava.

Table I. Pretreatment heart rate, mean arterial pressure, and blood gas values (mean ± SEM)

	n	*Heart rate*	*Mean arterial pressure*	*pH*	P_{CO_2}	P_{O_2}
Fetuses						
Arginine vasopressin	12	191 ± 8	42.1 ± 3.0	7.38 ± 0.02	41.6 ± 1.0	22.5 ± 1.7
Arginine vasopressin + vasoconstrictor antagonist	12	195 ± 9	44.0 ± 2.5	7.39 ± 0.02	42.4 ± 1.7	22.0 ± 0.8
Arginine vasopressin + nitroprusside	10	195 ± 9	39.7 ± 2.4	7.36 ± 0.01	44.4 ± 1.9	20.1 ± 1.0
Adults						
Arginine vasopressin	6	64 ± 4.2	70.2 ± 4.4	7.44 ± 0.05	33.9 ± 1.33	101.9 ± 8.64
Arginine vasopressin + vasoconstrictor antagonist	6	80 ± 5.3	75.5 ± 4.3	7.35 ± 0.06	33.0 ± 1.33	121.9 ± 12.64

An open-ended catheter was also inserted into the amniotic cavity for intrauterine pressure measurements. The aorta and vena cava of the pregnant ewe were cannulated via the left mammary artery and vein and the femoral artery and vein in the nonpregnant ewe. All maternal and fetal lines were filled with sterile heparin, closed with metal plugs, and exteriorized through a separate stab wound in the ewe's flank. The catheters were placed in a cloth pouch sutured to the ewe's skin. Five hundred milligrams of kanamycin was administered into the amniotic cavity on the day of operation, for the next 4 days, and then every other day. The ewe was given Combiotic (Pfizer), 0.1 ml · kg^{-1} intramuscularly on the day of operation, the next 4 days, and then every other day. Fresh heparin was placed in the vascular catheters daily. The animals were maintained in mobile metabolic carts.

Experimental protocol. All animals were allowed to recover at least 72 hours after operation before any experiments were undertaken. All experiments were done with the ewes awake and quiet. The vascular and amniotic catheters were opened and connected to Statham pressure transducers for monitoring fetal (in the pregnant animals) and adult (in the nonpregnant animals) phasic systolic and diastolic blood pressures and amniotic fluid pressures. Fetal and adult heart rates were obtained with cardiotachometers triggered by the arterial pulse wave. The pressures and heart rates were recorded continuously on a Beckman dynograph recorder. The animals were allowed a minimum of 30 minutes to acclimate to the experimental situation. All fetal arterial pressures reported below have been corrected for intra-amniotic pressure.

There were three experimental protocols as described below. Ten fetuses were studied in all three protocols. Two additional fetuses were studied in two protocols. All five nonpregnant ewes were studied in protocols 1 and 2. Initial placement in protocol 1, 2, or 3 was random. A total of 34 experiments were performed in the 12 fetuses, and 12 experiments were done in the five adult nonpregnant ewes. All experiments in the same animal were separated by at least 48 hours. Fetal weight was estimated according to the data of Joubert[11] for fetal weights at known gestational ages. Adult weight was obtained directly. Plasma vasopressin concentrations were measured by radioimmunoassay.[12]

Protocol 1: Arginine vasopressin infusion. Arginine vasopressin in sterile saline solution containing 0.1% bovine serum albumin was infused through a venous catheter at a rate of 8 ng $kg^{-1}min^{-1}$ for 30 minutes. The infused volume was constant in all fetuses at 0.103 ml min^{-1} and in all adults at 0.76 ml min^{-1}. Arterial blood (0.5 ml) was obtained just before the start of the infusion and at the end of the infusion for determination of blood gas, pH, and hematocrit. Blood gases were measured with a Radiometer blood analyzer with the use of appropriate electrodes. Heart rate and blood pressure were recorded continuously for 30 minutes prior to the beginning of the infusion, throughout the infusion, and for 1 hour after completion of the infusion.

Protocol 2: Arginine vasopressin infusion after pretreatment with an arginine vasopressin antagonist. The same procedure as in protocol 1 was carried out except that the animals were pretreated with a selective vasoconstrictor antagonist [1-(β-mercapto-β,β-cyclopentamethylene proprionic acid) 2-(0-methyl) tyrosine] arginine vasopressin, 30 to 175 μg kg^{-1}. The vasoconstrictor antagonist was given by intravenous bolus 15 minutes before the start of the arginine vasopressin infusion.

Protocol 3: Arginine vasopressin infusion with simultaneous infusion of sodium nitroprusside to control blood pressure. The same procedure as in protocol 1 was carried out except that sodium nitroprusside (250 μg/ml) was infused through a second venous line simultaneously with the arginine vasopressin infusion. The rate of infusion of sodium nitroprusside was adjusted in each

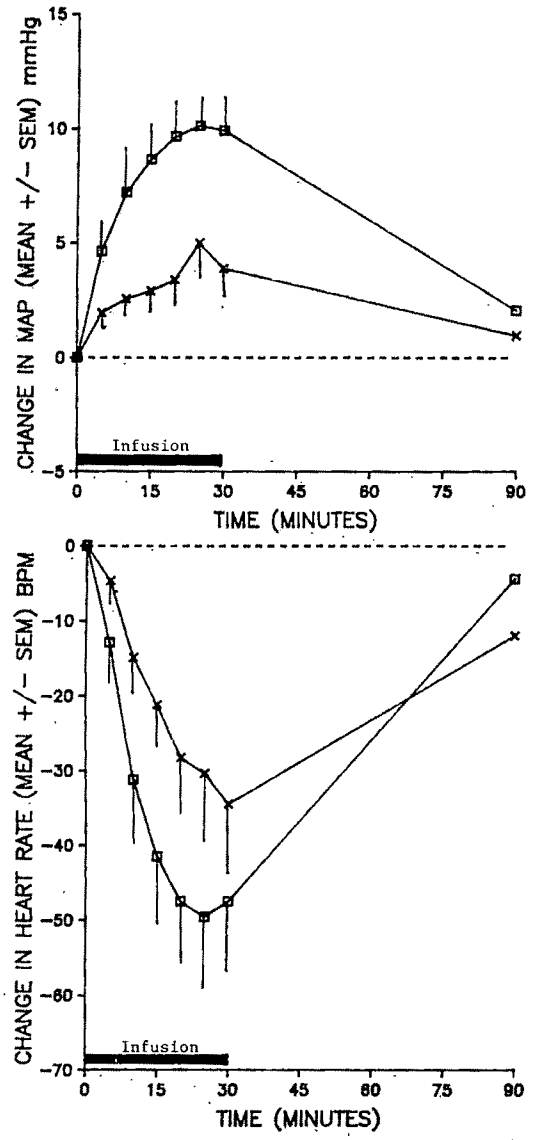

Fig. 1. Fetuses. *Top:* Change in mean arterial pressure *(MAP)* (mean ± SEM) with arginine vasopressin infusion alone (—□—) and with arginine vasopressin infusion after pretreatment with vasoconstrictor antagonist (—x—). Time error: F = 13.816, p = <0.001. Treatment error, F = 19.689, p = 0.001. *Bottom*: Change in heart rate (mean ± SEM) with arginine vasopressin infusion alone (—□—) and with arginine vasopressin infusion after pretreatment with vasoconstrictor antagonist (—x—). Time error: F = 14.450, p = <0.001. Treatment error: F = 1.733, p = .219.

animal to keep mean arterial pressure constant during the 30-minute arginine vasopressin infusion. Infusion rates ranged from 1.14 to 41.18 μg $kg^{-1} \cdot min^{-1}$.

Data analysis. The change in mean arterial pressures and heart rates were analyzed by use of two-way analysis of variance with repeated measures design. Hematocrit, blood gas values, resting heart rates, and mean arterial pressures were compared by means of the *t* test. All values are recorded as mean ± SEM.

Results

In both the fetuses and adults, resting heart rate, mean arterial pressure, arterial blood gas values, and hematocrits were not different among the different treatment groups (Table I) except resting heart rate in the adult arginine vasopressin treatment group was lower than resting heart rate in the arginine vasopressin plus arginine vasopressin antagonist treatment group (p = 0.035). Arterial blood gases and hematocrits did not change significantly during the infusions (data not shown). Plasma arginine vasopressin levels in the fetuses increased from a resting control value of 5.2 ± 1.1 to 113.2 ± 40.7 pg ml^{-1} at the end of the 30-minute infusion.

When arginine vasopressin alone was infused in the fetuses, mean arterial pressure increased 10.1 ± 1.1 mm Hg (Fig. 1). Administration of the vasoconstrictor antagonist did not alter fetal resting mean arterial pressure but did attenuate the pressor response to arginine vasopressin. Two-way analysis of variance revealed a significant effect of time (p < 0.001) and a significant difference between the two treatment groups (p = 0.001).

With arginine vasopressin alone, heart rate fell 50 ± 8 bpm. The vasoconstrictor antagonist did not change resting fetal heart rate and after pretreatment with the antagonist arginine vasopressin still produced a profound bradycardia that was not different from that observed when arginine vasopressin was infused alone.

When simultaneous infusions of sodium nitroprusside and arginine vasopressin were given to 10 fetuses, mean arterial pressure actually fell at 5, 10, 15, and 30 minutes (Fig. 2). By two-way analysis of variance, the change in mean arterial pressure was significantly different when compared with that associated with arginine vasopressin alone (p = 0.001). Heart rate still fell in this group and was not statistically different from the fall in heart rate with arginine vasopressin alone (p = 0.196).

Six pairs of experiments were carried out in five adult nonpregnant ewes for comparison (Fig. 3). Mean arterial pressure increased 18.6 ± 3.0 mm Hg with arginine vasopressin alone. After pretreatment with the vasoconstrictor antagonist, the peak increase in mean arterial pressure was 4.1 ± 1.6 mm Hg. Heart rate fell 30 ± 7 bpm with arginine vasopressin alone and 18 ± 5 bpm after pretreatment with the vasoconstrictor antagonist. By two-way analysis of variance, there was a significant effect of time on mean arterial pressure and a significant difference in the change in mean arterial pressure between the two treatment groups. There was also a significant effect of time on heart rate. There was no difference in fall in heart rate between the two treatment groups.

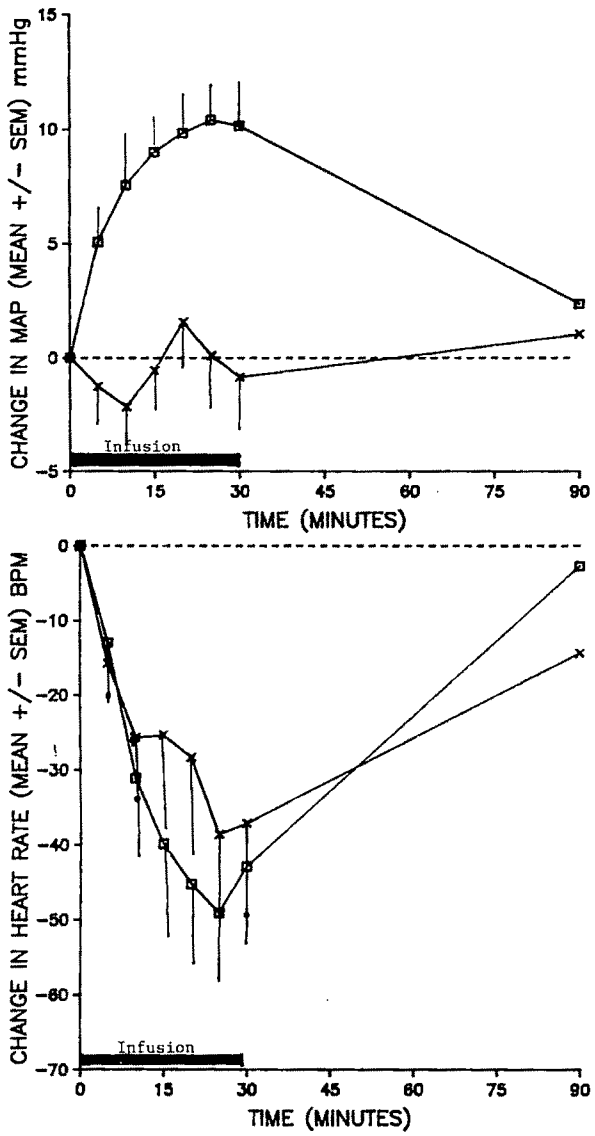

Fig. 2. Fetuses. *Top:* Change in mean arterial pressure *(MAP)* (mean ± SEM) with arginine vasopressin infusion alone (—□—) and with arginine vasopressin with nitroprusside (—x—). Time error: F = 2.231, p = 0.05. Treatment error: F = 233.54, p = 0.001. *Bottom:* Change in heart rate (mean ± SEM) with arginine vasopressin infusion alone (—□—) and with arginine vasopressin with nitroprusside (—x—). Time error: F = 10.020, p = 0.001. Treatment error: F = 0.553, p = NS.

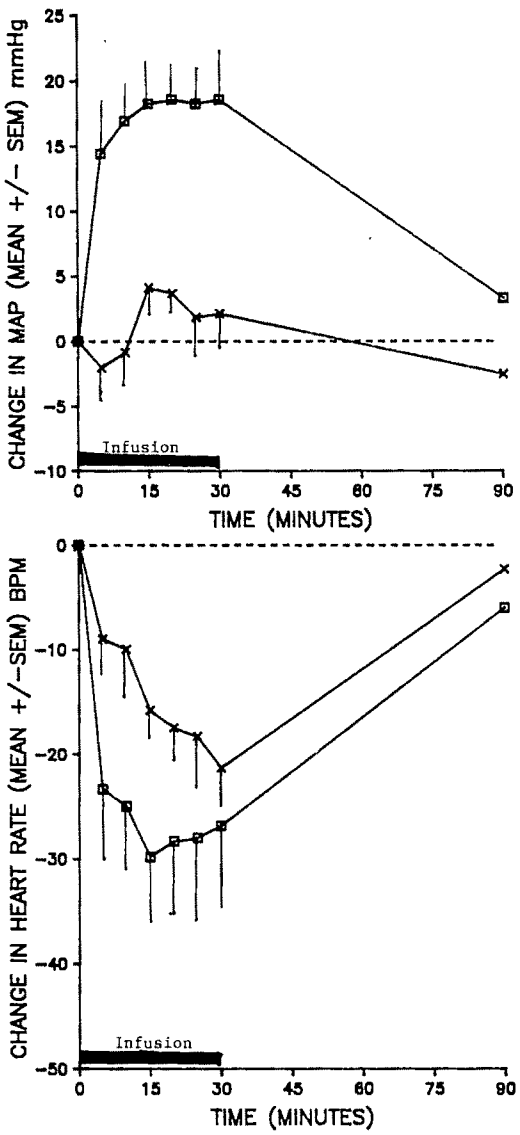

Fig. 3. Adults. *Top:* Change in mean arterial pressure *(MAP)* (mean ± SEM) with arginine vasopressin infusion alone (—□—) and with arginine vasopressin infusion after pretreatment with vasoconstrictor antagonist (—x—). Time error: F = 13.394, p = 0.05. Treatment error: F = 18.051, p = 0.008. *Bottom:* Change in heart rate (mean ± SEM) with arginine vasopressin infusion alone (—□—) and with arginine vasopressin infusion after pretreatment with vasoconstrictor antagonist (—x—). Time error: F = 9.591, p = <0.001. Treatment error: F = 3.445, p = 0.121.

Comment

Vasopressin increases arterial pressure and decreases heart rate when administered intravenously to fetuses.[6-8] Various stressful stimuli cause an increase in plasma concentrations of arginine vasopressin in the fetus, and it has been suggested that arginine vasopressin is a mediator of bradycardia associated with fetal distress.[7, 13] Our results demonstrate that, in both fetuses and adults, arginine vasopressin can produce bradycardia in the absence of an increase in blood pressure. This indicates that the bradycardia produced by arginine vasopressin is not simply a reflex response to an increase in arterial pressure. The observation is compatible with the report by Heyndrickx et al.[14] that arginine vasopressin, unlike angiotensin, reduced heart rate after denervation of arterial baroreceptors in conscious dogs. In addition, Varma et al.[10] also observed a pronounced bradycardia with arginine vasopressin in-

fusion in anesthetized dogs when systemic arterial pressure was controlled with a mechanical device.

The mechanism whereby arginine vasopressin can decrease heart rate when arterial pressure is held constant is not clear; however, it is known that arginine vasopressin can decrease heart rate in dogs in which both vagi are cut.[15] This suggests that peripheral infusions of arginine vasopressin can decrease cardioaccelerator activity. Such an effect may be mediated centrally since arginine vasopressin administered into the fourth ventricle produces no change in blood pressure but a decrease in heart rate in anesthetized dogs.[10]

Other possible mechanisms for the bradycardia associated with increased levels of arginine vasopressin include a direct negative chronotropic effect on the myocardial cells or myocardial ischemia due to coronary constriction. Scott et al.[16] found no significant differences between rat myocardial contraction frequency in tissue culture measured before and after addition of vasopressin. Myocardial blood flow in the fetal lamb has been reported to be unaffected during arginine vasopressin–induced bradycardia.[6]

Resting arginine vasopressin levels in the fetuses we studied (5.2 ± 1.1 pg $\cdot$ ml^{-1}) were similar to those of previous reports (4.81 ± 1.2 and 8.1 ± 2.6 pg $\cdot$ ml^{-1}).[6, 8] The mean arginine vasopressin clearance calculated from eight fetuses was 74.8 ml $\cdot$ kg^{-1} $\cdot$ min^{-1} and is also comparable to that of previous reports (60.5 ml $\cdot$ kg^{-1} $\cdot$ min^{-1}).[7]

The increase in mean arterial pressure of 10.1 ± 1.1 mm Hg and the decrease in heart rate of 50 ± 8 bpm with arginine vasopressin infusion in the fetuses are in agreement with the observations of others.[6-8]

The percent changes in mean arterial pressure in the fetuses and adult ewes were similar (23.8 versus 26.5). However, the percent change in heart rate was 47.6 in the adults versus 26.2 in the fetuses. This suggests that, while there is no difference in relative responsiveness to the pressor effects of arginine vasopressin between fetus and adult, the fetus is less sensitive to the negative chronotropic effect of arginine vasopressin. The adult animal is better able to maintain cardiac output by increasing stroke volume when heart rate falls than is the fetus.[17] This relative decrease in sensitivity may therefore be protective for the fetus.

Mirro et al.[18] observed that nitroprusside infusion in newborn lambs caused no change in heart rate while producing a significant decrease in mean arterial pressure. Nitroprusside causes an increase in heart rate in humans when used to control blood pressure[19] and has been shown to have no direct cardiac effects in dogs.[20] We therefore conclude that the bradycardia observed in these ovine fetuses given nitroprusside and arginine vasopressin simultaneously was an effect of arginine vasopressin.

In both the fetal and adult sheep the bradycardia produced by arginine vasopressin was not blocked by the vasoconstrictor antagonist. In contrast, Schwartz et al.[21] found in unanesthetized dogs that arginine vasopressin in the presence of the vasoconstrictor antagonist caused an increase in heart rate. They used a higher dose of arginine vasopressin (10 ng $\cdot$ kg^{-1} $\cdot$ min^{-1} for 60 minutes versus 8 ng $\cdot$ kg^{-1} $\cdot$ min^{-1} for 30 minutes) and a smaller dose of the vasoconstrictor antagonist (10 versus 30 to 175 μg $\cdot$ kg^{-1}). The pressor response was blocked in their animals with the vasoconstrictor antagonist. The differences in observations are probably due to species differences. It would appear that while in dogs the antidiuretic activity of arginine vasopressin produces cardiovascular effects opposite those produced by its vasoconstrictor action, this is not the case in sheep.

There was no significant effect of the vasoconstrictor antagonist on blood gas values, heart rate, or mean arterial pressure, indicating that vasopressin probably does not play a major role in circulatory regulation in the resting state.

In vivo and in vitro modulation of growth hormone and prolactin of a mixed somatotropic-lactotropic pituitary microadenoma

Eberhard K. Muechler, M.D., Ko-En Huang, M.D. Joseph V. McDonald, M.D., and Loretta Tang, Ph.D.
Rochester, New York

Both in vivo and in vitro responses of prolactin and growth hormone to stimuli were studied in an acromegalic, amenorrheic woman with a chromophobe adenoma of the pituitary gland. Preoperative testing revealed a prolactin rise after thyrotropin-releasing hormone and chlorpromazine and a decline after L-dopa and bromocriptine administration. During 3.5-hour incubations, cultured tumor cells produced significant increases of growth hormone and prolactin after dibutyryl adenosine 3',5'-cyclic monophosphate stimulation, while bromocriptine inhibited both hormones. (Am J Obstet Gynecol 1987;157:453-5.)

Key words: Mixed pituitary microadenoma, acromegaly, amenorrhea, growth hormone, prolactin

Recent studies have shown that hyperprolactinemia is found in 42% to 70% of all acromegalic patients. We observed a young woman with amenorrhea, headaches, increase in hand and foot size, and coarsening of facial features caused by a mixed pituitary microadenoma that produced both prolactin and growth hormone.

Case report

A 32-year-old, gravida 2, para 2 woman was referred because of secondary amenorrhea of 7 years' duration. She complained of occasional episodes of headaches and denied galactorrhea. For the last 2 years prior to referral the weight of the woman increased by 20 pounds, height increased by 2 inches, and shoe size increased by two numbers. Facial features were coarse and puffy. Watery fluid could be expressed from the left breast. Baseline laboratory studies included: prolactin, 81 ng/ml (normal 0 to 35 ng/ml); thyroxine, 9.7 μg/dl (normal 5 to 13 μg/dl); thyroid-stimulating hormone 3.3 μU/ml (normal 1 to 10 μU/ml); growth hormone, 13 ng/ml (normal 0 to 11 ng/ml); follicle-stimulating hormone, 4.8 mIU/ml (normal 2 to 20 mIU/ml); luteinizing hormone, 11.6 mIU/ml (normal 4 to 30 mIU/ml). Polytomography of the sella turcica and computed tomographic scanning showed a markedly enlarged volume with cortical erosion and severe slanting of the left sella floor. Visual field examination was normal. Three months later the patient underwent transsphenoidal removal of a pituitary chromophobe adenoma with a focal acidophilic component. Four weeks after operation a weight loss of 11

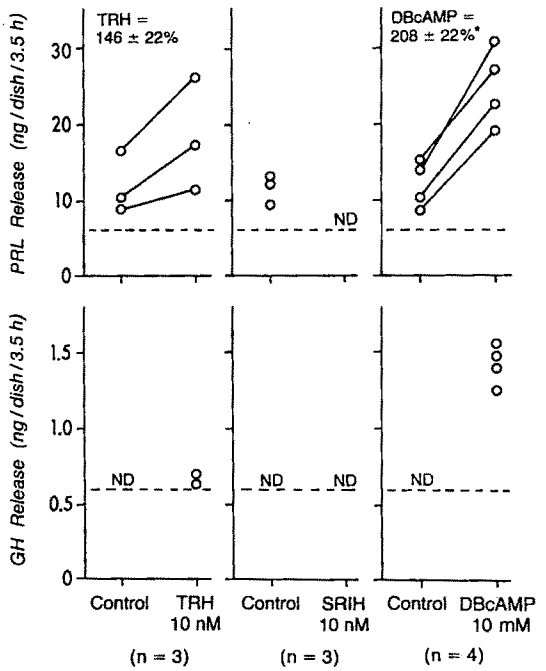

Fig. 2. Effect of thyrotropin-releasing hormone *(TRH)*, somatostatin *(SRIH)*, and dibutyrylcyclic adenosine monophosphate *(dbcAMP)* on prolactin *(PRL)* and growth hormone *(GH)* release by cultured cells. Day 4 cultures were incubated for two consecutive 3.5-hour periods. The initial incubation was in Dulbecco's modified Eagle's medium alone (control); the subsequent incubation was in Dulbecco's modified Eagle's medium containing 10 nmol/L thyrotropin-releasing hormone, 10 nmol/L somatostatin, or 10 nmol/L dibutyrylcyclic adenosine monophosphate. * = Significantly different from control period ($p < 0.05$). *Dotted line* indicates sensitivity of assay. *ND,* Not detectable.

pounds was observed, in addition to decreased puffiness of the face and all extremities and absence of headaches. Laboratory data were repeated at this time: growth hormone, 4.3 ng/ml; prolactin, 54 ng/ml; thyroxine, 9.5 μg/dl; thyroid-stimulating hormone, 3.1 μU/ml; follicle-stimulating hormone, 7 mIU/ml; luteinizing hormone, 6.3 mIU/ml. Seven months after operation amenorrhea was persistent. Headaches were lower in frequency and diminished in intensity when compared with those of the preoperative period. Prolactin had decreased further to a level of 30 ng/ml and growth hormone was not detectable.

Material and methods

On four consecutive days the patient was given test substances after an overnight fast. Serial blood samples were collected through an indwelling polyethylene catheter at 0, 30, 60, 120, 180, and 240 minutes after 100 gm of glucose was given orally. Blood samples were collected at −15, 0, 30, 60, 120, and 180 minutes after 500 mg of L-dopa orally, 0.5 mg of thyrotropin-releasing hormone intravenously, 2.5 mg of bromocriptine orally, and 25 mg of chlorpromazine intramuscularly. Growth hormone, prolactin, and thyroid-stimulating hormone were measured by established radioimmunoassays in the clinical laboratory of Strong Memorial Hospital in Rochester, New York. A portion of the removed pituitary gland was used to prepare monolayer cultures as described previously.[1] Concentrations of prolactin and growth hormone in the incubation media were determined by the double-antibody method of radioimmunoassay with materials

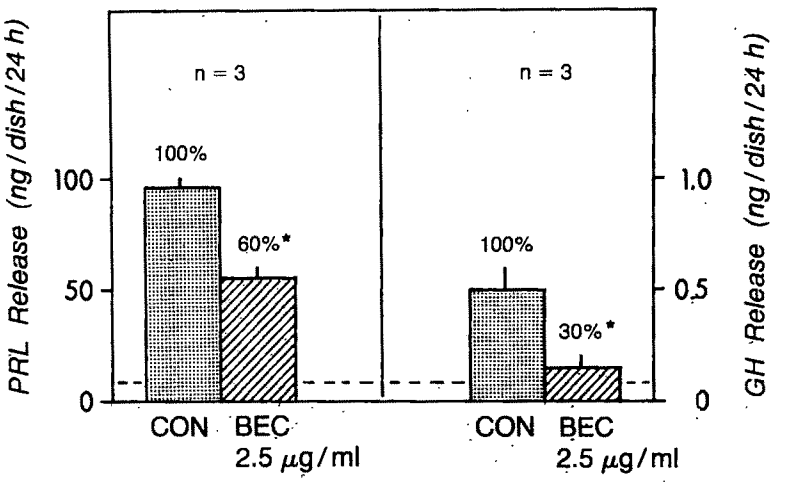

Fig. 3. Effect of bromocriptine *(BEC)* on prolactin *(PRL)* and growth hormone *(GH)* release by cultured cells. Day 14 cultures were incubated for two consecutive 24-hour periods. The initial control incubation was in Dulbecco's modified Eagle's medium supplemented with sera (10% horse serum, 5% fetal calf serum); the subsequent incubation was in the serum containing Dulbecco's modified Eagle's medium plus bromocriptine (2.5 μg/ml).

provided by the National Pituitary Agency, National Institutes of Health. Specific antibodies for prolactin and growth hormone were AFP-Ab-hRPL#1 and NIAMD-A-hGH (guinea pig), respectively.

Results

The in vivo response of thyroid-stimulating hormone to thyroid-releasing hormone was normal (baseline thyroid-stimulating hormone, 1.2 μU/ml; peak thyroid-stimulating hormone, 9.6 μU/ml after 30 minutes). All other in vivo results are summarized in Fig. 1. Cell cultures of tumor tissue were established and exposed to somatostatin, thyrotropin-releasing hormone, dibutyrylcyclic adenosine monophosphate, and bromocriptine. In vitro responses of prolactin and growth hormone to various agents are summarized in Figs. 2 and 3.

Comment

This study correlates in vivo and in vitro testing of pituitary function in a young woman with acromegaly and amenorrhea due to a mixed pituitary microadenoma. There was no change in growth hormone levels in vivo in response to L-dopa, bromocriptine, thyrotropin-releasing hormone, and glucose tolerance testing. Several other studies have shown that growth hormone is suppressed in acromegalic subjects by dopaminergic agonists such as L-dopa and bromocriptine. The known suppressive effect of dopaminergic drugs has led to long-term treatment with bromocriptine as an acceptable choice for treating acromegaly. The clinical and biochemical responses to surgical tumor ablation were satisfactory. The preoperative in vivo response of growth hormone and prolactin to stimuli was compared to in vitro responses of cultured cells. We observed a more consistent response of lactotropic cell function than of somatotropic cell function. While dibutyryl-cyclic adenosine monophosphate exhibited stimulating effects on prolactin and growth hormone in the cultured tumor cells, bromocriptine inhibited both hormones. Thyrotropin-releasing hormone stimulated release of prolactin and growth hormone only slightly (difference not statistically significant). A slight suppressive response to somatostatin was observed for prolactin only. Lamberts et al.[2] have demonstrated 39% inhibition of growth hormone by somatostatin in 12 of 15 pituitary tumor cell cultures from acromegalic subjects.

Several factors, such as a difference in dose, absorption, metabolic clearance, and duration of testing, may explain the discrepancy between the absence of a growth hormone response to stimuli in vivo and the presence of a selective response in vitro.

Local cerebral glucose utilization in fetal sheep exposed to noise

R. M. Abrams, Ph.D., A. A. Hutchison, M.B., Ch.B., K. J. Gerhardt, Ph.D., S. L. Evans, B.S., and J. Pendergast, Ph.D.
Gainesville, Florida

Rate of local cerebral glucose utilization in fetal sheep was measured in conditions of normal laboratory ambient sound (65 to 70 dB sound pressure levels) and broadband noise (105 and 120 dB sound pressure levels) delivered by two earphones situated on the abdominal surface of the ewe. Broadband noise had neither a visible effect on the ewe nor specific effects on the fetal arterial pH, Pa_{O_2}, Pa_{CO_2}, and plasma glucose concentration. However, glucose utilization of many cerebral structures was elevated in noise-exposed fetuses. (AM J OBSTET GYNECOL 1987;157:456-60.)

Key words: Fetus, sound, brain, glucose utilization

The effect of environmental sound on the human fetus in utero is of widespread interest. Developmental biologists speculate that prenatal auditory experiences have subtle but far-reaching implications in human postnatal speech recognition and behavioral maturation.[1] Conversely, among public health specialists there is concern about the possible deleterious effects on fetuses from noise in the workplace.[2] Broadband noise applied to the anterior abdominal wall of pregnant women can result in increased fetal heart rate,[3] blink-startle reflexes,[4] and fetal movements that persist beyond the period of sound stimulation.[5]

In an earlier study we measured the energy metabolism of the fetal sheep brain in normal laboratory sound conditions.[6] Of all the cerebral structures examined, the brain stem auditory nuclei and pathways had some of the highest rates of glucose utilization. We inferred from these clinical and animal findings above that sound is likely to be a major sensory input for the fetus.

The link between cerebral activity evoked by a specific sensory input and the metabolic rate of the specific structures and pathways involved in processing the stimulus is well understood in animals postnatally.[7] Apart from one study[8] of carbon 14–labeled deoxyglucose in central auditory structures in gerbils at various times after birth, there is little known about the metabolic correlates of function in these structures during their ontogeny.

In the present study we measured fetal local cerebral metabolism during the application of intense broadband noise applied by earphones to the shaved abdomen of the pregnant ewe. The aim was to determine if the metabolism in the central auditory pathway was increased above its already high level. An unexpected finding was the metabolic activation of some nonauditory structures, suggesting a diffuse activation of the developing brain by acoustic stimuli.

Methods

Fifteen pregnant, grade Western ewes at 130 to 135 days of gestation were anesthetized with halothane. Catheters were placed in the fetal brachiocephalic artery and superior vena cava and in the maternal iliac artery and inferior vena cava as previously described.[7] Ewes were cart trained during the daily removal and reinstillation of heparin (500 U/ml) in the catheters.

On the day of the experiment to measure local cerebral glucose utilization in fetuses, an experimental ewe and a companion ewe were placed in carts and wheeled to an adjacent empty room. Each of the eight sound-exposed animals was fitted with a 3-inch-wide folded sheet encircling the abdomen and flanks. The sheet contained two TDH-39 earphones (Royal Industries, Phoenix, Arizona) spaced 6 inches on either side of the ventral midline at the level of the anterior aspect of the thigh. Earphones and amplifiers were calibrated with a standard NBS 9A coupler and B & K pressure microphone (Bruel & Kjaer, Marlborough, Massachusetts) to produce broadband noise at inten-

sities of 105 and 120 dB sound pressure level (referenced to 20 μPa). The spectrum was flat to 6000 Hz and began to roll off at approximately 26 dB per octave above that frequency. The sound-exposed animals and seven unfitted control animals stood quietly during a 2-hour preexposure period.

Control samples of fetal and maternal arterial blood were drawn for analyses of glucose concentrations, background carbon 14 levels, P_{O_2}, P_{CO_2}, pH, and hematocrit. Earphones were then activated. Five minutes later, at time zero, 200 to 300 μCi of 2-deoxy-D-[^{14}C]glucose ([^{14}C]DG), specific activity 50 to 56 μCi/mol (American Radiolabeled Chemicals Inc., St. Louis, Missouri), in 2 to 3 ml of physiologic saline solution, warmed to body temperature, was injected into the fetal venous catheter (dead space, 0.6 ml) over 15 to 30 seconds. The injection was followed by a 2 ml flush of saline solution over 10 to 20 seconds. Sampling from the fetal arterial catheter was begun at time zero. Usually five samples of 0.6 ml each were taken during the first minute to characterize the plasma [^{14}C]DG levels that increased and decreased rapidly during and after infusion. Approximately eight additional blood samples were taken at increasing intervals for 40 minutes, after which time the sound was turned off and both fetus and ewe were deeply anesthetized with barbiturate and then killed with an intravenous injection of saturated potassium chloride. The deep vaginal temperature of the mother was measured immediately.

The fetal brain was removed as quickly as possible, frozen in Freon XII at −50° C, and stored at −80° C. Plasma glucose concentration and plasma carbon 14 levels were measured according to published procedures.[6] A computer program (provided by Drs. L. Sokoloff and C. Kennedy, National Institute of Mental Health) was used to calculate the final tissue [^{14}C]DG and the final integrated tissue-specific activity for both gray and white matter.

Brains were sectioned at 20 μm in a Bright cryostat (Bright Instrument Company, Limited, Huntingdon, Combs, England). The distance advanced during a cutting cycle was verified by micrometry. Three consecutive sections out of 28 were mounted on coverslips, dried immediately, and exposed along with National Institute of Mental Health standardized, carbon 14 incorporated plastic discs (Amersham Corp., Arlington Heights, Illinois) to Kodak SB-5 film for 7 days. The density of brain structure and discs was determined with a densitometer equipped with a 0.5 mm aperture (Sargent-Welch Scientific Co., Skokie, Illinois).

Homogeneity of densities within many structures, for example, in the hypothalamus, mamillary body, caudate, putamen, superior colliculus, lateral geniculate, reticular formation, optic chiasm, and corona radiata, required only bilateral readings in three to four sections to obtain a representative average value. Structures with marked heterogeneity of densities, that is, the hippocampus and vermis, were surveyed in a random fashion to obtain an unweighted average of values. In smaller heterogeneous structures, including the brain stem nuclei, the average of single readings of highest density in each of six to eight sections was recorded.

A calculation of tissue content of [^{14}C]DG was performed with National Institute of Mental Health calibrated Amersham plastic standards. The lumped constant used, 0.401, was determined in earlier experiments in fetal and newborn sheep.[6] Local cerebral glucose utilization in micromoles per 100 gm per minute was calculated according to the formula published by Sokoloff et al.[7]

The Wilcoxon rank sum test for unpaired data was used to compare data collected on control fetuses with data on sound-treated fetuses ($p < 0.05$). For the purposes of this test, no distinction was made between those fetuses receiving 105 dB and those receiving 120 dB sound pressure levels.

Results

Two animals from sound stimulation experiments were not included in the statistical analysis of local cerebral glucose utilization. Distended cerebral ventricles were found in one fetus during the sectioning procedure. No explanation or cause for this hydrocephalus could be found. In a second fetus, intermittent, position-related difficulties in drawing blood from the arterial catheter necessitated vigorous palpation of the abdomen of the ewe to force movement of the fetus during the sampling procedure. The possibility that vestibular or tactile stimulation might have altered local cerebral glucose utilization was considered. In both cases, however, local cerebral glucose utilization was within the ranges found in the remaining six sound-stimulated fetuses.

The gestational ages, fetal weights, number of days after operation, fetal blood gas determinations, fetal plasma glucose levels, and maternal temperature in the experimental and control groups were not significantly different (Table I).

In all structures evaluated mean local cerebral glucose utilization was higher in sound-stimulated animals as a group than in control animals (Table II). However, the significance of these differences was variable because of considerable overlapping in local cerebral glucose utilization values. Of the brain stem auditory nuclei, only the cochlear nuclei showed a significant sound-induced rise in glucose utilization. Other structures exhibiting a rise that reached significance ($p < 0.05$) were vestibular nuclei, inferior olives, habenula,

Comment

The effects on the human fetus of environmental sound are well-known. Thus sound-induced fetal movements[5, 9] and fetal cardioacceleration[10, 11] usually, but not always, follow an intense pure tone or broadband of tones applied to the anterior abdominal wall. Generally, the sound source is applied directly over the fetal head as palpated or seen in ultrasound scans.

To understand more fully the importance of sound in human prenatal development, we have used the fetal sheep as a model. First, we measured the metabolic rate of the fetal central auditory structures in normal laboratory sound conditions.[6] Glucose utilization in these structures was higher than most structures in the fetal sheep brain. Rates of utilization in the cochlear nucleus, superior olives, lateral lemniscus, and inferior colliculus rose rapidly near the beginning of the third trimester and remained high until term, after which there was a 50% increase. In contrast, utilization of glucose in the brain as a whole rose more linearly throughout the last third of gestation.

In subsequent experiments[12] we documented a significant decrease in local cerebral glucose utilization during administration of ketamine and thiopental to induce anesthesia. Also we characterized the sound environment of the fetus[13] and confirmed that it was richer and more varied than previously thought.[14, 15] In fact, sounds with frequencies below 2 kHz were attenuated very little.[13-15]

In the present study we attempted to determine if sound presented to the surface of the abdomen could produce any increase in central auditory metabolic rate, from which we could infer that neuronal activity along this pathway was enhanced. There is ample documentation that sound results in a significant rise in glucose utilization in brain stem nuclei subserving the auditory system,[16-18] but there was no mention in the literature reviewed of an enhancement in the nonauditory structures.

The reason many fetal gray and white matter structures, which are nonspecific for the auditory system, appeared to be affected by sound is not readily understood, but functional activity in specific pathways may not be a prominent feature during the early stages of development. Myelinization proceeds in a rostral direction; before its completion, auditory stimulation may result in a nonspecific, diffuse stimulation of metabolic activity in many brain structures. This widespread, sound-induced requirement for free energy may be vital for normal growth and development of the brain.

The earphones used in this study produced very high intensity broadband noise but over a relatively small area. If the fetal head were not directly in this field and close to the sound source, some attenuation of sound would be expected. The abdomen and pregnant uterus are not acoustically uniform. Also to be considered as a source of the large variability in the local cerebral glucose utilization results would be the predominant behavioral state during the time that local cerebral glucose utilization was measured. Both fetal brain oxygen consumption[19] and glucose utilization[20] are increased during low-voltage electrocortical activity. A clearer picture of the specific and general effects of sound as a useful test for fetal neuronal function should emerge if both the position of the fetal head and the fetal behavioral state are known.

We gratefully acknowledge the advice and assistance of Drs. C. Kennedy, C. Oliver, J. Hicks, and K. Bzoch, and Messrs. R. Trustee and R. Cooper.

Transplacental stimulation of functional and morphologic fetal rabbit lung maturation: Effect of thyrotropin-releasing hormone

Uday Devaskar, M.D., Kenneth Nitta, M.D., Karl Szewczyk, M.D., H. Farouk Sadiq, M.D., and Daphne deMello, M.D.

St. Louis, Missouri

We investigated the effect of maternally administered thyrotropin-releasing hormone on functional and morphologic fetal lung maturation. Thyrotropin-releasing hormone (40 μg/kg/day) or the vehicle was injected intravenously into the New Zealand White rabbit does on days 25, 26, and 27 of gestation. On day 27 of pregnancy, the does were killed and the fetuses were delivered. The functional pulmonary maturity was assessed by pressure-volume hysteresis while morphologic maturity was assessed by histologic techniques. Enhanced functional and morphologic fetal lung maturation was noted in animals treated with thyrotropin-releasing hormone when compared with controls. An important role of thyrotropin-releasing hormone in fetal lung maturation is proposed. (AM J OBSTET GYNECOL 1987;157:460-4.)

Mammalian fetal lung development can be influenced by several hormones including corticosteroid, insulin, androgens, estrogens, catecholamines, epidermal growth factor, prolactin, thyroid hormones, and thyrotropin-releasing hormone (TRH).[1] Glucocorticoids administered antenatally to women in premature

labor reduce the risk of hyaline membrane disease in premature neonates.[1] However, the beneficial effect of corticoids may be dependent on time, fetal sex, and gestational age.[1] Corticosteroids are relatively contraindicated when pregnancy is complicated by placental insufficiency, premature rupture of the amniotic membranes, maternal infection, or diabetes.[2] All of these situations are frequently encountered clinically.

Administration of TRH into the rabbit doe results in an increase in total phospholipid and phosphatidylcholine in the fetal lung lavage, while the phosphatidylcholine/sphingomyelin ratio increases from 1.0 to 2.2.[3] These changes in the fetal lung lavage phospholipid content and composition are suggestive of increased lung maturation. Although the clinical use of TRH, alone or in combination with corticosteroids, has been suggested for the prevention of hyaline membrane disease,[3] the mechanisms of the effects of TRH, its influence on other parameters of fetal lung development, and the possible side effects remain unclear. Rooney et al.[3] postulated that the administration of TRH to the rabbit doe lends to its transfer across the placenta, which in turn stimulates fetal thyroid activity.[3] However, the demonstration of placental transfer of TRH or the quantitation of fetal plasma thyroid hormones was not performed.[3] In this study we investigated whether administration of TRH to the rabbit doe results in its passage across the placenta. In addition, we investigated the effect of maternal administration of TRH on functional and morphologic fetal lung development, fetal lung glycogen content, and maternal and fetal plasma total triiodothyronine and free thyroxine concentration. From the results we conclude that TRH crosses the rabbit placenta from the mother to the fetus and that functional and morphologic fetal lung development can be accelerated transplacentally by maternal administration of TRH.

Material and methods

Animal care and euthanasia. Pregnant New Zealand White rabbits of known gestation time (0 = time of breeding; term = ~31 days) were purchased from a local supplier, housed individually, and allowed to drink water and eat Rabbit Chow (Purina, St. Louis, Missouri) as desired. To investigate whether TRH crosses the placenta, we injected 10 μCi of iodine-125–labeled TRH [(Pyro)Glu-His-Pro-NH2, molecular weight 486.3, specific activity 2200 Ci/mmol, New England Nuclear, Boston, Massachusetts] per doe (n = 3) on day 27 of gestation. Maternal arterial blood was collected 10 minutes before and 1, 5, 10, 20, 30, 60, and 90 minutes after the intravenous injection of ^{125}I-labeled TRH. The does were killed with intravenous pentobarbital (100 mg/kg) and the fetal blood was collected after decapitation.[5] The radioactivity in 400 μl of the plasma was counted in a gamma radiation counter (Packard Instruments, Downers Grove, Illinois) for 2 minutes. The degradation of ^{125}I-labeled TRH was assessed by 50% trichloroacetic acid precipitation.

To investigate the effect of maternal administration of TRH (L-pyroglutamyl-L-histidyl-L-prolinamide, molecular weight 362.4, Sigma Chemical Co., St. Louis, Missouri) on fetal lung development, TRH (40 μg/kg/dose) or an equivalent volume of normal saline solution was injected intravenously between 8 and 9 AM on days 25, 26, and 27 of pregnancy. Forty-five minutes after the third dose, the does were killed by intravenous pentobarbital. Immediately before the animals were put to death, maternal blood was collected from the ear artery. The uterus was exposed after laparotomy. The three to four fetuses on the extreme right of the uterus were killed with 10 mg each of intramuscular pentobarbital through the uterine wall. The rest of the fetuses were delivered and immediately decapitated. Free-flowing blood was collected for the measurement of total triiodothyronine and free thyroxine.[5] A reliable assay for plasma TSH and total thyroxine in rabbit plasma was not available. Lungs from the decapitated fetuses were collected for the quantitation of glycogen.[5] Pentobarbital-injected fetuses were delivered with the amniotic sac and placenta intact and used for the pressure-volume hysteresis.

Pressure-volume curve. The method of performing dynamic pressure volume curve experiments on the closed chest rabbit fetuses has been described.[6] The blunt needle of a 19-gauge butterfly needle was inserted into the trachea and fixed in place with silk. The other end of the butterfly needle was attached to a three-way stopcock that was connected to a manometer and to a 10 ml graduated syringe via thin plastic tubing. The syringe was mounted on a Harvard pump (Harvard Apparatus Co., South Natic, Massachusetts) that is capable of infusing and withdrawing. The lungs were gradually inflated with air to 40 cm H_2O and then deflated slowly to 0 cm H_2O. The lungs were deflated to −30 cm H_2O to remove residual air and then equilibrated to 0 cm H_2O. The lungs were again inflated to 40 cm H_2O. After equilibration at an inflation pressure of 40 cm H_2O, the lungs were gradually deflated to 0 cm H_2O. The pressure on the manometer was recorded after each 0.4 ml of air was withdrawn. The total lung capacity (that is, the amount of air injected in the lung during the second inflation) and the stability of the lung during the second deflation at 0, 5, 10, 20, 35, and 40 cm H_2O were derived. After the pressure-volume experiment the lungs were dissected, gently blotted to remove excess fluid, and weighed. These lungs were fixed at atmospheric pressure by immersion in 10% paraformaldehyde.

were embedded in Parafilm, and 6 μm sections from each block were stained with hematoxylin and eosin. In addition to conventional microscopic examination, lung volume proportions were analyzed with an integrating eyepiece of the point-counting type, as per the principles outlined by Chalkley.[7] The relative volume (V) of alveolar lumen (al) and the interalveolar septa (ias) was determined.[7] The alveolar expansion index (Ia) was calculated as follows:

$$Ia = \frac{Val}{Vias}$$

Statistical analysis

Results

The trichloroacetic acid precipitability of radioactivity in fresh ^{125}I-labeled TRH was ~60%. The TCA precipitability of radioactivity in the maternal and fetal plasma after 90 minutes of ^{125}I-labeled TRH injection was also ~60% in all three experiments. These results imply that there was no degradation of ^{125}I-labeled TRH during this period. The amounts of radioactivity (counts per minute per 0.4 ml) in the maternal plasma were 100 ± 5, 12,000 ± 3000, 10,000 ± 2000, 8000 ± 1500, 6000 ± 1000, 4800 ± 600, 2600 ± 300, and 1800 ± 150, respectively, at 10 minutes before and 1, 5, 10, 20, 30, 60, and 90 minutes after an intravenous bolus of 100 μCi of ^{125}I-labeled TRH. The mean radioactivity in 0.4 ml of fetal plasma in all treated animals was higher (1800 ± 100 cpm) than the control (90 ± 5, n = 3, $p < 0.001$). It can be concluded that TRH crosses the rabbit placenta from the mother to the fetus.

There were no obvious undesirable effects in the mother or the fetuses after TRH treatment. None of the TRH-treated or control does delivered prematurely. All does in control and TRH groups gained 200 ± 6 gm (n = 11) and 195 ± 8 gm (n = 10), respectively, from 25 to 27 days of gestation. Fetal weight, fetal lung glycogen, and fetal and maternal plasma triiodothyronine and free thyroxine concentrations were similar in control and TRH-treated animals (Table I).

The lung–to–body weight ratio and the total lung capacity among control and TRH group fetuses were not significantly different (Table II). The stability of the fetal lungs during deflation at 0, 5, 10, and 20 cm H_2O pressure in TRH-treated animals was higher than that in the control group (Table II, $p < 0.05$).

On histologic examination a clear difference between TRH-treated and control fetal lungs was noted (Fig. 1). Alveolar air expansion was more pronounced in TRH-treated fetuses. The alveolar expansion index in control fetuses (0.61 ± 0.032, n = 48) was less than that in TRH-treated fetuses (0.77 ± 0.069, n = 48) ($p < 0.05$).

Comment

Controversy has been expressed as to whether TRH can cross all mammalian placentas.[8] TRH crosses the placenta of the rat, rhesus monkey, and human.[8] In contrast to these studies, a report claimed lack of placental transport of TRH in sheep.[9] In the present study we have shown that TRH crosses the placenta from the mother to the fetus in the rabbit. The difference in the placental transport of TRH among these mammalian species may be due to the different structures of the placenta. While the human, monkey, or rat placenta is hemochorial, the sheep placenta is epitheliochorial.[10] The rabbit placenta can be hemochorial or hemoendothelial.[10]

Fetuses from TRH-treated does demonstrated enhanced functional and morphologic lung maturation. These results further support the hypothesis that TRH may be important in fetal lung development.[3] Increased stability of lungs on deflation in TRH-treated fetuses may be due to increased availability of alveolar surfactant, changes in connective tissue elasticity, or the degree of alveolation or a combination of these factors. Pressure-volume experiments with saline solution infusion would have been helpful but were technically difficult. Since TRH administration has been shown to enhance secretion of pulmonary surfactant in the fetal rabbit at a similar gestational age,[3] it is likely that the stability of the lungs on deflation in TRH-treated fetuses in the present study was due to increased alveolar surfactant.

Maternal and fetal plasma thyroid hormone concentrations in TRH-treated animals were similar to control values. It can be concluded that an increase in maternal

or fetal plasma thyroid hormone does not occur within 45 minutes of TRH administration in rabbit. Although no data are available in the rabbit, an increase in maternal or umbilical cord plasma thyroid hormone concentration after maternal administration of TRH did not occur until 3 to 4 hours in the human.[11] It is possible that maternal and/or fetal plasma thyroid hormone concentrations did increase after the first two doses of TRH on days 25 and 26 of pregnancy, but this possible surge in the plasma thyroid hormone concentration was not sustained enough to be seen on day 27. On the other hand, it is conceivable that enhanced fetal lung maturation from TRH stimulation may occur without a significant stimulation of fetal thyroid hormone activity. Surfactant production and/or release may be under neurohumoral control.[1] TRH has been shown to serve as a neurotransmitter and therefore may act independently of the fetal pituitary-thyroid axis.[3] The human placenta produces TRH and TRH has been demonstrated in both maternal and fetal plasma.[12, 13] Maternal plasma concentrations of TRH increase during pregnancy and TRH administered to the pregnant woman stimulates the fetal pituitary-thyroid axis.[11, 14] Although the physiologic significance of these observations remains unclear, it is possible that TRH may be important in the maturation of the human fetal lung.

Acceleration of fetal lung maturation after TRH therapy has not yet been determined to improve respiratory function and enhance survival after premature delivery. Whether simultaneous administration of TRH and corticosteroids does indeed have an additive effect in enhancing fetal lung maturation remains to be examined. Future animal experimentation seems necessary before a clinical trial of TRH, alone or in combination with corticosteroids, is initiated.

We thank Dr. William J. Keenan for review of the manuscript.

The effect of severing the spinal cord of fetal lambs on length of gestation

Romana A. Nowak, Ph.D., Susan E. Samaras, B.S., Mary C. Chorney, M.S., D.V.M., Daniel R. Hagen, Ph.D., and Philip J. Dziuk, Ph.D.
Urbana, Illinois

Lambs with spinal cords that had been severed near the head at 50 days of gestation were born after a shortened gestation of about 128 days. Lambs with severed spinal cords born as a twin with an intact lamb had a normal gestation of 148 days. The presence of an intact spinal cord or the signals that it might carry apparently influence the length of gestation in the ewe. (Am J Obstet Gynecol 1987;157:464-7.)

The normal fetal hypothalamic-pituitary-adrenal axis has been shown to influence initiation of parturition in sheep. Infusion of adrenocorticotropic hormone (ACTH) but not other pituitary hormones caused pre-

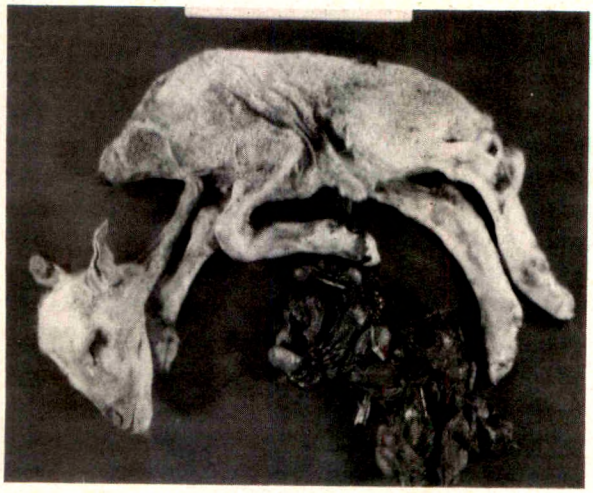

Fig. 1. Lamb born at 145 days of gestation with only a strand of vascular tissue joining the head and body. Separation was done at 45 days of gestation.

mature delivery in 4 to 7 days.[1] Liggins et al.[2] showed that hypophysectomy of fetal lambs resulted in delayed parturition presumably because of absence of secretions from the fetal adrenal cortex. These experiments showed that an intact fetal pituitary-adrenal axis was important for the initiation of parturition in sheep.

How the increases in fetal ACTH and subsequently fetal corticoids are initiated is unclear. The possible role of neurosecretory hormones from the hypothalamus or posterior pituitary gland has not been investigated thoroughly. When the anterior pituitary gland was destroyed or removed in fetal lambs,[2] the posterior pituitary was undoubtedly also removed. Decapitation of a sheep fetus delayed parturition,[3] but in this case the posterior pituitary gland and the brain were also removed. Schriefer et al.[4] observed that the content of oxytocin in pituitary glands from neonatal rats was reduced by parturition, which indicated possible release of oxytocin from the fetal posterior pituitary gland during labor. In addition, administration of an oxytocin antibody to rat fetuses but not to their mothers increased the length of gestation by 18 hours. Oxytocin in the plasma of fetal lambs was significantly higher than in the mother just before parturition.[5] Neurophysins associated with both oxytocin and vasopressin have been described in the fetal sheep pituitary gland.[6] Alexander et al.[7] showed that hypoxia was effective in causing vasopressin release, which was accompanied by an increase in neurophysin and ACTH. It is possible that these neurophysins are the triggering stimuli for oxytocin, vasopressin, and ACTH release before parturition.

In a preliminary experiment we disrupted the normal neural path of fetal lambs by severing the spinal cord in the upper cervical area. Parturition occurred but with varied gestation. Thus the involvement of a neural signal to the fetal hypothalamic-pituitary-adrenal axis may influence initiation of parturition. We performed the following studies in an attempt to understand the involvement.

Table I. Mean length of gestation and weight of intact lambs, lambs with severed spinal cords, or lambs with pinched tracheas

Treatment	*Length of gestation (days)*	*Weight (kg)*
Pinched trachea	149 ± 1.7	3.8 ± 0.3*
Severed spinal cord	128 ± 2.3*	1.86 ± 0.04*
Twins, one intact and one severed	147 ± 0.8	3.2 ± 0.07 (intact) 2.9 ± 0.1 (severed)
Intact control	148 ± 1.6	3.2 ± 0.06

Values are expressed as the mean ± SEM.
*Indicates that value is significantly different from control ($p < 0.05$).

Material and methods

Preliminary study. In the preliminary study an attempt was made to decapitate fetal lambs at about 45 days of gestation in 29 ewes in the same manner as in fetal pigs.[8] Decapitation resulted in fetal death and resorption in all but one case. This one lamb was born after 145 days of gestation. It weighed 1397 gm, was edematous, had no wool, the neck stump was healed, and the intestines contained pastelike material. In several other lambs in which decapitation was attempted, a remnant of vascular tissue connected the head and the body (Fig. 1). These lambs were born after various periods of gestation, ranging from about 100 to 160 days. One lamb with a crushed but intact head weighed 8 kg at 174 days of gestation, when it was removed by hysterotomy. Thus complete decapitation was ordinarily fatal, but disruption of the usual neural pathway was not, provided a vascular connection persisted between the head and the body. To pursue the observations further, a subsequent study was conducted in which the spinal cord was severed in a systematic and uniform manner.

Animals. Forty-six mature crossbred ewes were maintained outdoors under a normal seasonal photoperiod. During the breeding season crossbred rams that wore marking harnesses were introduced into the flock. Ewes were observed daily for marks. Ewes were considered pregnant if they were not marked again. The age of the fetus was verified by palpation at operation.

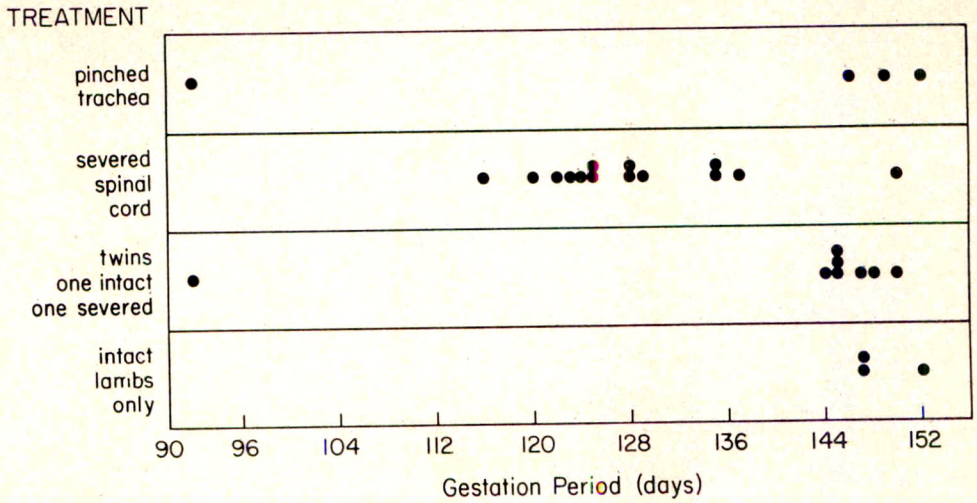

Fig. 2. Gestation for each ewe that contained lambs treated as indicated at 50 to 70 days of gestation.

Animals were cared for and used under the guidelines of the National Institutes of Health for such animals.

Experimental design. Ewes were assigned at 50 to 70 days of gestation to one of four treatment groups: (1) intact control—laparotomy with no surgical manipulation was performed on the fetus; (2) fetal sham operation—the ventral aspect of the neck and trachea of the fetus was pinched and crushed; (3) the spinal cord of the fetus was severed; (4) the spinal cord of one fetus was severed, whereas the twin fetus was left intact.

Anesthesia was induced with an intravenous injection of 17 ml of pentobarbital sodium solution (65 mg/ml, Holmes Serum Co., Springfield, Illinois) and maintained with halothane and a closed-circuit anesthesia apparatus.[9] The ovaries and uterus were exposed through a midventral incision and the number of corpora lutea and fetuses recorded. Spinal cord transections were performed by grasping the fetus through the uterine wall, orienting the fetus by palpation, and then severing the cord with thumb and forefinger in the cervical area. The spinal cord was severed as close to the head as possible, usually between C-1 and C-3. The ventral aspect of the neck and trachea was pinched in a similar manner in the second treatment group. All ewes were observed daily for delivery of lambs.

Lambs were weighed after delivery. The spinal cord was examined grossly to determine the completeness of transection. The lungs were removed and placed in water to determine flotation. The digestive tract was examined for the presence of meconium. Lambs in which the trachea had been pinched were examined to determine the extent of the crushing of the trachea and that the spinal cord was intact.

Statistical analysis. Results were analyzed with Student's t test. Differences were considered significant when $p < 0.05$.

Results

Seventeen of the 46 ewes aborted within a few days of operation or died several weeks after operation from causes unrelated to treatment. Results for the remaining 29 ewes are presented in Fig. 2 and Table I. Fig. 2 shows the gestation for ewes in the four treatment groups. Two ewes aborted at 92 days of gestation. Ewes that carried only lambs with severed spinal cords had a significantly shorter gestation than ewes in the other treatment groups ($p < 0.05$). This effect was consistent except for one lamb that was delivered after a normal period. However, lambs with severed spinal cords that were twins of intact lambs were delivered after a normal gestation with their intact mates.

Two of the four lambs with pinched tracheas were very edematous and died at birth. Alcorn et al.[10] reported a similar phenomenon in lambs in which the trachea was ligated between 105 and 110 and 120 to 148 days of gestation. Two were born alive but were killed because of severe breathing difficulties. Lambs with severed spinal cords appeared quite normal grossly and had normal wool. The spinal cord of each lamb had been severed cervically at C1-3. Lungs did not float, verifying that these lambs did not breathe. All lambs had meconium in the intestines.

The weights of lambs in the different treatment groups are shown in Table I. Lambs with severed spinal cords weighed less than controls, presumably in association with the short gestation. However, weights of lambs with severed spinal cords that were twins to intact lambs did not differ significantly from those of their intact counterparts. Lambs with pinched tracheas had

greater weights than controls because of the excess fluid retained by these lambs.

Comment

The significant finding of this study is that transection of the spinal cord of fetal lambs resulted in a shortened gestation to about 128 days. However, in cases in which lambs with severed spinal cords were twins to an intact lamb, both were delivered after a normal period of gestation.

Our finding of shorter gestations in lambs with severed spinal cords was unexpected. Binns et al.[11] reported a congenital cyclopian type of malformation associated with prolonged gestation in fetuses of range sheep in Idaho that had ingested *Veratrum californicum* (skunk cabbage). The affected lambs had pituitary glands, although the neural connections were either missing or abnormal. Decapitated pig fetuses have a prolonged gestation of 124 to 125 days.[8] Decapitated sheep fetuses were born at term or later.[3] However, Honnebier and Swaab,[12] who examined the influence of anencephaly of human fetuses on length of gestation, reported that a number of these fetuses were born prematurely at 34 to 36 weeks of gestation.

In the present study, the lambs with severed cords were dead at or shortly after birth when found during frequent inspections. It seems unlikely that intrauterine death precipitated parturition in view of the fact that lambs with severed spinal cords and a normal twin were born after a normal gestation. Also lambs with severed spinal cords did not weigh less than the normal twin or other intact controls but did weigh more than the single lambs with severed spinal cords born at 128 days of gestation.

In studies by Liggins et al.[13] and Dawes et al.,[14] spinal cord transections were performed at 115 to 123 days of gestation. No effect on gestation was detected, since lambs were delivered either spontaneously at term or by hysterotomy.

In the present study, lambs with severed spinal cords and an intact twin had a normal gestation. A similar phenomenon was observed in pigs by Stryker and Dziuk,[8] who found that a litter consisting of a ratio of more than one intact fetus to four decapitated fetuses had a normal gestation. Length of gestation was normal when a hypophysectomized lamb was a twin to an intact lamb.[2] In all cases it appears that the intact fetus can override whatever effect decapitation or severing of the spinal cord has on length of gestation.

Several studies[15, 16] of litters of lambs that contain fetuses of different genetic background have found that the fetus of the genetically shorter gestation can often influence the length of gestation of its twin. Fetal endocrine changes in a mixed breed pregnancy were largely controlled by the fetal twin with a shorter gestation.[16]

The results of our study show that transection of the spinal cord of fetal lambs at the cervical level at 50 to 70 days of gestation causes a shortened length of gestation. This effect is overridden by the presence of an intact fetus. Because no endocrine assessments were made, we can only conjecture as to the cause of the shortened gestation. However, the results of this study do support the idea that neural input can affect the length of gestation.

The effects of proteolytic enzymes on in vitro ovulation in the rabbit

Yasunori Yoshimura, M.D., Rosemary Santulli, B.S., Susan J. Atlas, Ph.D., Shingo Fujii, M.D., and Edward E. Wallach, M.D.

Baltimore, Maryland

The involvement of proteolytic enzymes in follicle rupture was assessed by use of the in vitro perfused rabbit ovary. Streptokinase (10 and 100 units/ml) induced ovulation in the absence of gonadotropin. Ovulation failed to occur in contralateral control ovaries. The time of ovulation in streptokinase- and human chorionic gonadotropin—treated ovaries was similar, but significantly more ova from streptokinase-treated ovaries were immature ($p < 0.001$). Other ovaries were pretreated with trans-4-(aminomethyl)-cyclohexane-carboxylic acid, an inhibitor of the conversion of plasminogen to plasmin, and then perfused with human chorionic gonadotropin (50 IU). Ovulatory efficiency was significantly reduced by trans-4-(aminomethyl)-cyclohexane-carboxylic acid at 10 or 1 mmol/L ($p < 0.001$), but ovum maturity was unaffected. Aprotinin (100 or 10 μg/ml), a potent inhibitor of plasmin, significantly inhibited human chorionic gonadotropin–induced ovulation ($p < 0.001$) but did not affect oocyte maturation. Scanning electron microscopy of detergent-treated streptokinase-perfused ovaries revealed loosening and decomposition of collagen in the tunica albuginea. These results suggest proteolytic enzyme involvement in follicle rupture. (Am J Obstet Gynecol 1987;157:468-75.)

Key words: Perfused ovary, proteolytic enzymes, ovulation

Ovulation is a complex phenomenon, involving oocyte maturation, follicular steroidogenesis, rupture of the graafian follicle, and release of mature ova.[1] Follicle rupture is preceded by disruption of connective tissue in the apex of the follicle wall. The decomposition of this tissue has been postulated to be dependent on proteolytic enzyme activity.[2] Collagenolytic enzymes, present in rat graafian follicles in the process of ovulation, are thought to play a significant role in disruption of the follicle wall.[3] Strickland and Beers[4] have hypothesized that gonadotropins induce ovulation by stimulating the synthesis of a plasminogen activator in mature ovarian follicles. Plasminogen activator acts on plasminogen in the follicular fluid and tissue to produce plasmin, which, in turn, weakens follicular wall tissue. These observations have not, however, proved conclusively that follicle rupture is a direct result of the action of plasminogen activator and/or other proteolytic enzymes. In contrast, recent observations raise questions about the specific role of plasminogen activator in the process of ovulation.[5] Indomethacin can inhibit ovulation in the rat while failing to significantly reduce ovarian plasminogen activator activity. These data suggest that plasminogen activator may not be the critical proteolytic enzyme for follicle rupture. The role of proteolytic enzymes in the mechanism of ovulation thus remains to be clarified. An isolated perfused ovary preparation has been effective in studying local factors involved in the ovulatory process and in evaluating the effects of specific agents on phenomena associated with ovulation.[1] The present study was designed to determine the effects of proteolytic enzymes on the processes of follicle rupture and oocyte maturation by means of an in vitro perfused rabbit ovary model.

Material and methods

Fifty-two sexually mature New Zealand White female rabbits were isolated for a minimum of 3 weeks prior to the experimental procedure. The rabbits were caged individually under controlled light and temperature with free access to Purina Rabbit Chow and water. Rabbits weighing at least 3.5 kg were anesthetized with intravenous pentobarbital sodium (32 mg/kg), given heparin sulfate (120 units/kg) for anticoagulation, and then subjected to laparotomy. Overies were excluded from study if they appeared immature or if 50% or more of the surface follicles appeared hemorrhagic. Each ovarian artery was cannulated in situ, and the ovary with ovarian artery and vein and supportive adi-

pose tissue was removed and placed in a perfusion chamber. Each ovary was perfused with 150 ml of tissue culture medium 199 (M. A. Bioproducts, Walkerville, Maryland) supplemented with insulin, heparin, streptomycin, and penicillin. The cannulation procedure and perfusion apparatus have been previously described in detail.[6]

Ovaries were periodically observed for evidence of follicle growth and rupture. A follicle was considered ruptured when the cumulus containing an ovum was observed protruding from the ovarian surface. The ovulated ovum surrounded by its cumulus mass was carefully recovered from the ovarian surface. At 12 hours after exposure to ovulation-inducing substances, follicular oocytes were recovered from mature follicles (>1.5 mm in diameter) and the experiment was concluded. Both ovulated ova and follicular oocytes were assessed for stage of maturity and signs of degeneration as previously described.[6] The degree of ovum maturity was expressed as the percentage of oocytes that had achieved germinal vesicle breakdown. Ovulatory efficiency, defined as the percentage of mature follicles that proceed to rupture, was calculated for each group.

Experiment 1: Effects of streptokinase on ovulation and oocyte maturation. The initial experiment was designed to determine if exposure to streptokinase, an exogenous plasminogen activator, would induce ovulation in the absence of gonadotropin. Streptokinase (Sigma Chemical Co., St. Louis, Missouri) at a concentration of 1, 10, or 100 units/ml was added to the perfusate of one ovary. The contralateral ovary of each rabbit was simultaneously perfused in a separate chamber with medium alone and served as a control. Six rabbits were used for each dose. Ovaries were observed throughout the 12 hours of perfusion for evidence of follicle growth and rupture. In a companion experiment, ovaries were perfused with human chorionic gonadotropin (hCG) (50 IU) or with streptokinase (100 units/ml) in order to compare the ovulatory efficiency in hCG- and streptokinase-induced ovulation.

Experiment 2: Effects of trans-4-(aminomethyl)-cyclohexane-carboxylic acid on hCG-induced ovulation and oocyte maturation. The second experiment was designed to determine if trans-4-(aminomethyl)-cyclohexane-carboxylic acid (tAMCHA), a potent inhibitor of the conversion of plasminogen to plasmin, blocks hCG-induced ovulation. tAMCHA (Sigma Chemical Co.) at a concentration of 1 or 10 mmol/L was added to the perfusate of one ovary. The contralateral ovary of each rabbit was simultaneously perfused in a separate chamber with medium alone and served as a control. Thirty minutes after the onset of perfusion, 50 IU of hCG was added to the perfusate of both ovaries. Six rabbits were used at each dose level. Perfused ovaries were observed for 12 hours after exposure to hCG.

Experiment 3: Effects of aprotinin on hCG-induced ovulation and oocyte maturation. The third experiment was designed to determine if aprotinin, a protease inhibitor, blocks hCG-induced ovulation. Aprotinin (Sigma Chemical Co.) at a concentration of 10 or 100 μg/ml was added to the perfusate of one ovary. The contralateral ovary, which served as a control, was perfused with medium alone. Thirty minutes after the onset of perfusion, 50 IU of hCG was added to the perfusate of both ovaries. Six rabbits were used at each dose level.

Experiment 4: Surface morphologic features of ovarian follicles perfused with streptokinase. After perfusion with 100 units/ml streptokinase, ovaries from four rabbits were treated with the detergent sodium dodecyl sulfate according to the method described by Martin and Miller-Walker.[7] The first ovulation in this system occurred at approximately 5 hours after the onset of perfusion. Therefore perfusion was terminated at 4 and 7 hours after exposure to streptokinase (100 units/ml) in order to observe the morphologic alterations of the follicle during the process of ovulation. Perfused ovaries were placed in 5% sodium dodecyl sulfate in distilled water for 5 to 6 minutes and fixed

in 2.5% glutaraldehyde in 0.1 mol/L cacodylate buffer (pH 7.4) for 3 hours. The fixed ovaries were treated with 0.02% deoxyribonuclease for 1 hour at 20° C and then processed for examination with an Amray 1200 scanning electron microscope.

Statistical analysis. All data regarding the time of ovulation and ovulatory efficiency are presented as the mean ± SE. Statistical analysis was determined by use of Student's *t* test. The χ^2 test with Yates' correction was used to assess the percent degeneration and the percent germinal vesicle breakdown of follicular oocytes and ovulated ova.

Results

Experiment 1: Effects of streptokinase on ovulation and oocyte maturation. Streptokinase at a concentration of 10 or 100 units/ml, but not at 1 unit/ml, induced ovulation in the absence of hCG, whereas ovulation did not occur in any of the control ovaries (Table I and Fig. 1). The majority of ova ovulated in vitro did not progress beyond the germinal vesicle intact stage after treatment with streptokinase. In contrast, > 80% of ovulated ova from hCG-treated ovaries achieved an advanced stage of maturity (Table II). The ovulatory efficiency was significantly increased when ovaries were perfused with concentrations of streptokinase above 10 units/ml ($p < 0.05$). The time interval from ovulatory stimulus to ovulation was similar in streptokinase- and hCG-treated ovaries (Table II). At 100 units/ml of streptokinase, ovulatory efficiency was, however, significantly lower than that observed in the contralateral hCG-treated ovaries ($p < 0.02$). Examination of ovulated ova and follicular oocytes for evidence of degeneration showed no significant difference between

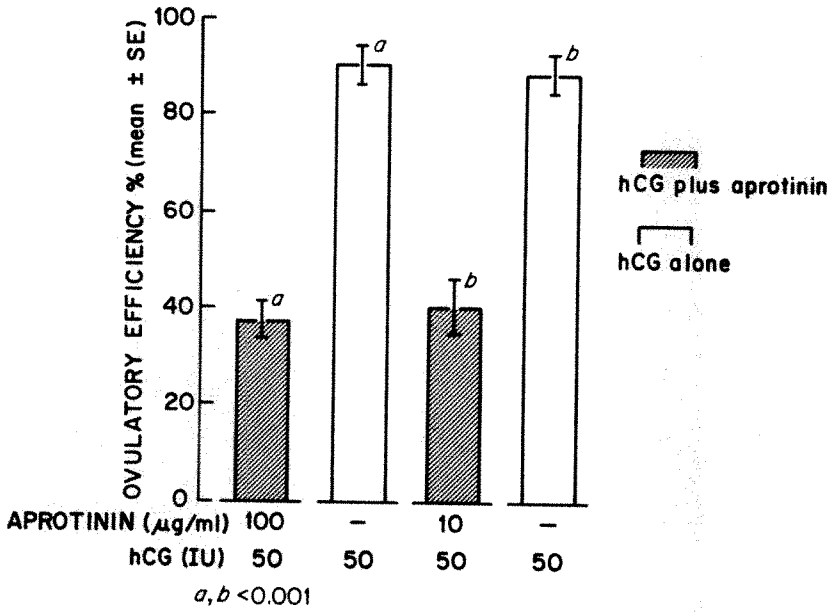

Fig. 3. Ovulatory efficiency of ovaries perfused with hCG plus aprotinin or with hCG alone. One ovary of each rabbit was perfused with medium alone. The contralateral, experimental ovary was perfused with aprotinin at a concentration of 10 or 100 μg/ml. Thirty minutes after the onset of perfusion, hCG (50 IU) was added to the perfusate of both ovaries. Groups identified by like letters were significantly different (*a*, *b* = $p < 0.001$).

groups within each series of experiments (Tables I and II).

Experiment 2: Effects of tAMCHA on hCG-induced ovulation and oocyte maturation. Addition of tAMCHA at a concentration of 1 or 10 mmol/L to the perfusate, together with 50 IU of hCG, resulted in an effective blockade of ovulation when comparison was made with ovaries exposed to hCG alone. Ovulatory efficiency was significantly reduced in ovaries exposed to tAMCHA as compared with control ovaries ($p < 0.001$) (Fig. 2). Addition of tAMCHA at 1 mmol/L to the perfusate significantly delayed the time interval to ovulation in ovaries exposed to hCG when compared with control ovaries treated with hCG alone ($p < 0.01$) (Table III). The percentage of ovulated ova and follicular oocytes achieving germinal vesicle breakdown did not differ significantly between tAMCHA-treated and control ovaries. Although the percentage of ovulated ova and follicular oocytes that showed evidence of degeneration was increased in tAMCHA-treated ovaries as compared with control ovaries, these differences were not significant.

Experiment 3: Effects of aprotinin on hCG-induced ovulation and oocyte maturation. Aprotinin at a concentration of 10 or 100 μg/ml significantly inhibited hCG-induced ovulation ($p < 0.001$) (Fig. 3). The mean

time of ovulation was delayed in aprotinin-treated ovaries as compared with control ovaries. This difference, however, was not significant (Table IV). Aprotinin at both concentrations did not affect the maturity of ovulated ova and follicular oocytes in ovaries perfused with hCG. The percentage of ovulated ova and follicular oocytes that showed evidence of degeneration was greater in aprotinin-treated ovaries than in control ovaries; however, this difference was not significant.

Experiment 4: Surface morphologic features of ovarian follicles perfused with streptokinase. The detergent sodium dodecyl sulfate is effective in removing surface epithelial cells in the rabbit ovary, allowing examination of the integrity and distribution of subepithelial tissue in the preovulatory follicle. At 4 hours after exposure to streptokinase, sodium dodecyl sulfate treatment revealed the honeycomb-like architecture characteristic of the basal lamina (Fig. 4). Degenerative change in the subepithelial connective tissue was not prominent at the apex of the follicle. At 7 hours after streptokinase exposure, sodium dodecyl sulfate treatment revealed defects associated with degeneration of the basal lamina. Collagen fibrils located near the lateral margin of the apex were compact, forming several bun-

dles or wide bands. The apical region was covered by distended thin collagen fibrils, resulting from degeneration or decomposition of connective tissues in the tunica albuginea (Fig. 5).

Comment

Many serine proteases and protease inhibitors that are thought to be involved in the process of follicle rupture may be present physiologically in vivo.[8] Plasma serine protease inhibitors such as α_1-antiplasmin, α_2-macroglobulin, and α_1-antitrypsin react rapidly and irreversibly with plasmin, inhibiting its protease activity.[9] Such humoral factors are excluded in this study because the perfusion system used lacks plasma or cellular blood components. This ovarian perfusion preparation can serve as an effective model for exploring the direct effects of agents on the process of ovulation while eliminating the possibility of systemic influences.[1, 10]

The sequence of events following gonadotropin stimulation that culminates in rupture of the graafian follicle and release of a mature ovum has been the subject of considerable attention. Steroid hormones, prostaglandins, inflammatory mediators including proteolytic enzymes, and ovarian smooth muscle have been implicated as participants in the process of follicle rupture.[1] The cumulative data indicate that an essential prerequisite for follicle rupture is the decomposition of the collagenous layers of the follicle.[2, 3, 7]

The present study of the in vitro perfused rabbit ovary preparation has demonstrated that streptokinase, an exogenous plasminogen activator, induces ovulation in the absence of gonadotropin. Strickland and Beers[4] have proposed the hypothesis that gonadotropins induce ovulation by stimulating the synthesis of a plasminogen activator in mature ovarian follicles. The data reported herein support the involvement of plasminogen activator in the mechanism of follicle rupture. The failure of streptokinase to induce ovulation with an efficiency comparable to that of hCG suggests that other components within the preovulatory follicular environment may also be required for follicle rupture. The relative inefficiency of streptokinase when compared with hCG may be related to the bacterial origin of this enzyme; native mammalian tissue plasminogen activator produced in response to hCG may be more active in vivo.

Streptokinase exerts its plasminogen activator activity after formation of a complex with plasminogen.[11] That the addition of streptokinase alone to the perfused ovary can induce ovulation implies that the ovary contains plasminogen, which binds to the exogenous streptokinase and produces an activated complex responsible for the observed effects. Streptokinase treatment was associated with degradation and decomposition of collagen fibrils within the tunica albuginea of preovulatory follicles. The results of the present study suggest that the plasminogen activator–plasmin system may lead to the activation of collagenase, thereby resulting in the disruption of follicular integrity necessary for ovum release.

The latent period between exposure to the stimulatory agent and time of ovulation did not differ significantly between ovaries treated with hCG and streptokinase; nonetheless significant differences in oocyte maturational stage were observed. These results imply that the appropriate factors necessary for oocyte maturation are lacking in streptokinase-induced ovulation. The failure of ova to undergo germinal vesicle breakdown and further maturation after exposure to streptokinase indicates that the phenomena of oocyte maturation and follicle rupture are dissociated in ovaries treated with plasminogen activator. Other agents have also been shown to evoke follicle rupture without leading to ovum maturation in this system.[10] Furthermore, this study demonstrates that exposure to serine protease inhibitors significantly reduces ovulatory efficiency in ovaries treated with hCG but does not affect oocyte maturation elicited by hCG administration.

tAMCHA has been reported to inhibit the activation

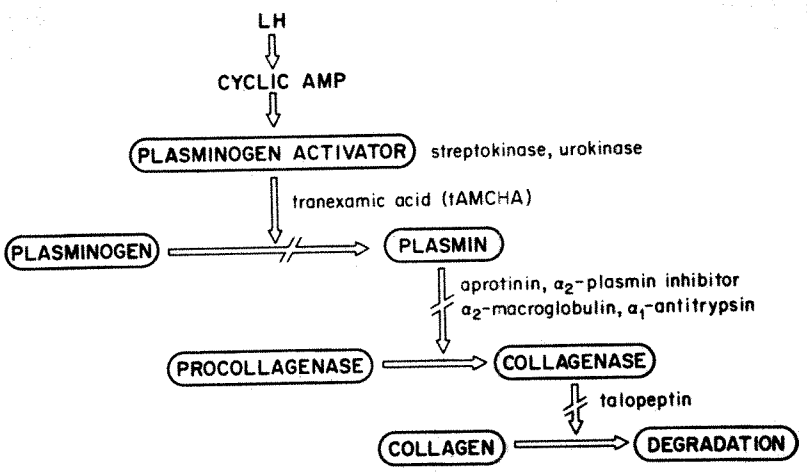

Fig. 6. Proposed scheme for involvement of proteolytic enzymes in disruption of the wall of the ovarian follicle.

of plasminogen to plasmin and fibrinolysis by active plasmin.[12] Aprotinin, a pancreatic trypsin inhibitor, inhibits plasmin and other serine proteases.[13] Ovulatory efficiency after hCG administration is significantly reduced by exposure to serine protease inhibitors. These data are consistent with the report that various microbial protease inhibitors completely block ovulation in the explanted hamster ovary.[14] The results of the present study provide further support for the role of serine protease(s) in the process of follicle rupture. However, the failure of antiplasmin agents to completely block hCG-induced ovulation suggests that other components, in addition to the plasmin-generating system, participate in follicle rupture.

Espey[8] has hypothesized that the preovulatory gonadotropin surge may induce mammalian ovulation by initiating an inflammation-like reaction in mature ovarian follicles. The role of common mediators of inflammation, such as prostaglandins and histamine, in the process of follicle rupture has been demonstrated in previous studies with the perfused rabbit ovary preparation.[10] Other reports provide evidence that ovulation can occur despite significant inhibition of plasminogen activator activity.[5] The plasminogen activator–plasmin system may contribute to collagenolysis in connective tissues of the ovarian follicles, but the present data cannot exclude the possibility of the involvement of inflammatory mediators other than the plasmin-generating system in the process of follicle wall disruption.

In conclusion, we propose a working model for the mechanism of follicular wall disruption in mammals (Fig. 6), which is a modification of the model suggested by Espey.[8] After the gonadotropin surge, plasminogen activator, which is responsible for plasmin formation, is produced by granulosa and theca cells.[15, 16] An elevation of the level of plasminogen activator in the follicle yields increasing intrafollicular concentrations of plasmin. The presence of plasmin and other serine proteases leads to the activation of latent collagenase, resulting in the degradation of collagenous connective tissue in the follicle. A series of enzyme systems acting locally alters the structural integrity of the follicle wall and facilitates follicle rupture.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Disruption of embryonic and fetal development due to preimplantation chemical insults: A critical review

Philip M. Iannaccone, M.D., Ph.D., Nancy L. Bossert, B.A., and Camille S. Connelly, B.A.
Chicago, Illinois

Descriptive teratology has developed several fundamental precepts, two of which can now be challenged on the basis of experimental evidence. The first is that prior to implantation the developing embryo is not susceptible to survivable defects from chemical injury. The second is that developmental defects cannot be due to mutational events since rare events seem unlikely to explain alterations in large populations of cells. This review presents current experimental evidence demonstrating that the effects of chemical exposure on blastocyst stage embryos may be manifest long after the time of insult and that subtle nonlethal mutations may have a role in poor fetal performance after early chemical exposures. (Am J Obstet Gynecol 1987;157:476-84.)

Key words: Preimplantation, mammalian embryology, teratology, pregnancy outcome

The tragic consequences of thalidomide use during pregnancy made the susceptibility of the developing fetus to chemical exposure abundantly clear. Many chemicals, some found frequently in our environment, have been described as teratogens. Many of these teratogens are now avoided and thus represent less of a threat to modern pregnancies than at other times. However, maternal smoking remains a major source of fetal exposure to environmental toxicants during gestation. Simpson[1] reported the first clear association of maternal smoking with adverse effects on the developing fetus. This work demonstrated a significant dose-dependent association between maternal smoking and premature birth. A clear association between maternal smoking and perinatal mortality, spontaneous abortion, and sudden infant death syndrome as well as maternal complications has been demonstrated.[2] Traditional studies of this association have examined mechanisms of fetal disruption during organogenesis and later gestational periods. Many studies aimed at understanding the relationship of smoking to pregnancy complications, both maternal and fetal, have concentrated on the direct toxic effects of nicotine in late gestation.[3, 4] However, tobacco and tobacco smoke contain a number of highly mutagenic substances. Indeed, nicotine itself can be metabolized to form mutagens.[5]

It has been generally held that prior to implantation, the embryo is insensitive to developmental program shifts as a result of chemical exposure.[6, 7] Recent studies have shown this concept to be an oversimplification. In this review we describe the possible role that mutations during preimplantation development may play in poor pregnancy outcome.

Preimplantation development

The preimplantation period of development in mammals is the time from fertilization to implantation (Fig. 1). The length of this period varies with different species. The preimplantation period is about 7 days in length in humans, 4 days in mice, and 5 days in rats. In many mammalian species, at this stage of development, the embryo is 100 μm in diameter, is associated with two polar bodies remaining from meiotic division, and is surrounded by a chemically complex structure called the zona pellucida. The zona pellucida is a highly refractile, noncellular coat consisting of mucopolysaccharides and sialic acid residues. The zona pellucida is important to early development for several reasons. Penetration of the egg by the fertilizing spermatozoon is accompanied by changes in the zona that help prevent polyspermic fertilization. The zona provides a constraint to cleavage and ensures that as the blastomeres divide they remain together and in the proper orien-

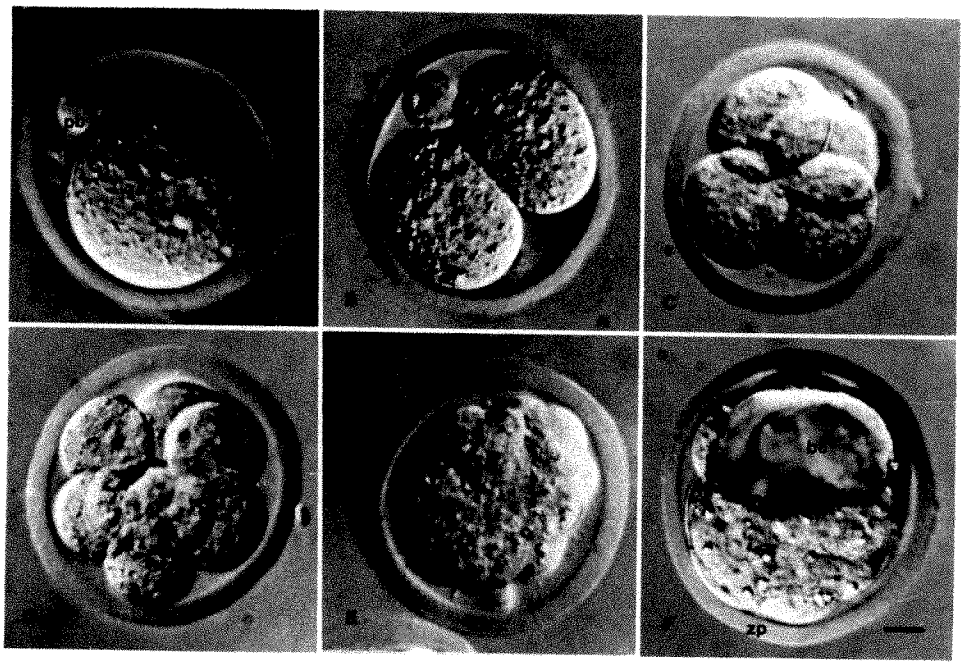

Fig. 1. Photomicrographs of living preimplantation mouse embryos (Hoffman modulation contrast optics). *A*, Pronuclear stage, single-cell embryo approximately 9 hours after fertilization. Both the maternal *(m)* and paternal *(p)* pronuclei are visible in the center of the embryo. The embryo is surrounded by the zona pellucida (*zp* in panel *F*). One polar body *(pb)* is still visible. *B*, First cleavage stage, two-cell embryo approximately 33 hours after fertilization. *C*, Four-cell embryo, approximately 48 hours after fertilization. *D*, Eight-cell embryo, before compaction, approximately 54 hours after fertilization. *E*, Postcompaction, eight-cell embryo approximately 60 hours after fertilization. *F*, Blastocyst stage embryo, approximately 86 hours after fertilization. All embryos are approximately 100 μm in diameter. *Bar* = 20 μm.

tation. The zona also prevents the embryo from adhering to the wall of the oviduct.

Mitotic cleavage division occurs entirely in the oviduct of most mammals, including man. The dividing embryo traverses the oviduct as the combined result of ciliary motion and muscular contraction. Divisions are symmetrical and reductive, resulting in a geometric increase in the number of blastomeres while the embryo remains a constant size. Prior to the eight-cell stage embryos in some mammalian species appear to have equivalent, totipotent blastomeres.[8, 9]

During early cleavage (the late eight-cell stage in the mouse) the embryo undergoes compaction, the morphogenetic process by which an embryo progresses from a collection of rounded, loosely associated blastomeres into a spherical embryo.[10] Individual blastomeres change shape and flatten against one another, thus maximizing the amount of cell-to-cell contact. Compaction appears to involve three steps: cell surface recognition and attachment of a ring of lateral microvilli to adjacent blastomeres, subsequent microfilament shortening in these lateral microvilli, and maintenance of the compacted, polarized state, which results in apical localization of microvilli on each blastomere. Compaction seems to be reversible and can be reinduced, but polarization of microvilli can occur only once.[10]

Prior to compaction, sister blastomeres of mouse embryos exhibit ionic coupling and possess cytoplasmic bridges that admit both fluorescein and horseradish peroxidase, a large molecule unable to cross gap junctions. Blastomeres from different mitotic pairs do not have demonstrable intercellular pathways. Intercellular communication mediated by gap junctions is first detected in the compacted eight-cell mouse embryo. At this stage, ionic coupling is observed and fluorescein injected into one cell is distributed to all eight cells of the embryo.[11] Gap junction formation does not appear to require concurrent protein synthesis since inhibition of protein synthesis by cycloheximide treatment fails to block gap junction construction.[12]

The increase in cell number from the eight-cell to the 16-cell stage necessitates that a certain number of cells occupy the interior of the morula and are completely separated from the outside by other cells. The external cells create a microenvironment in which the internal cells develop. These microenvironmental differences due to geographic location are the basis for the "inside-outside" hypothesis formulated by Tar-

kowski and Wroblewska.[8] This hypothesis states that the differentiation of blastomeres into trophoblastic and inner mass cells depends on the position of the blastomeres within the embryo. The "inside-outside" hypothesis is best supported by the experiments of Hillman et al.[13] In these experiments, embryos and parts of embryos were combined during early preimplantation stages. Each blastomere of a four-cell embryo could form both the trophectoderm and the inner cell mass of the blastocyst. However, when individual blastomeres of a four-cell embryo were placed on the outside of other four-cell embryos, they usually formed the outside layer of the blastocyst and went on to develop into the trophoblast and the yolk sac. Similar results were seen with eight-cell embryos.

Subsequent to compaction, polarization, and gap junction formation, zonular tight junctions are formed between peripheral blastomeres. The resulting barrier allows for the development of a fluid-filled cavity (blastocele) within the embryo. This is the beginning of the blastocyst stage of development. The blastocele enlarges as cells in this area degenerate, until the embryo resembles a hollow sphere. It comprises a single layer of large, flat cells on the periphery, called the trophectoderm or trophoblast, and an eccentric aggregate, known as the inner cell mass. The trophectoderm will develop into extraembryonic tissues, including the placenta, and is responsible for implantation and invasion of the maternal uterine tissue. The inner cell mass will develop into the fetus.

Implantation begins in the late blastocyst stage of the developing embryo. Implantation can be viewed as a process with at least three major phases. The first is the attachment phase, in which receptors on the trophectoderm are responsible for tight binding to endometrial epithelium. The second phase is invasion. In man, the trophectodermal cells invade through the basement membrane of the uterine epithelium to establish an implantation site in the stroma of the endometrium. In the mouse and rat, the endometrium engulfs the attached blastocyst, which results in an interstitial implantation. The third phase is the endometrial response to the implanted embryo. In a few eutherian species (including man, primates, and murine rodents) the uterine stromal cells undergo a specific reaction called decidualization, whereby the stromal cells in the immediate area of the embryo become large, eosinophilic, and transcriptionally active. The cells of the decidual swelling may be important in support of pregnancy and in suppression of immune rejection of the implanted embryo.[14, 15] Furthermore, decidual prolactin may be involved in the regulation of amniotic fluid volume,[16] and decidual luteotropin (a prolactin-like hormone in the rat) has been implicated in the maintenance of the corpus luteum.[17, 18]

Embryonic dysfunction

There is a significant waste of human life due to fetal loss. While there are approximately 3×10^6 live births a year in the United States, there are approximately 6×10^5 spontaneous abortions. Ten percent of the live births are premature and 13% of the infants have low birth weights. There are approximately 3×10^4 perinatal deaths, and about 2.6×10^4 children do not survive into their second year.[19]

The causes of poor pregnancy outcome have long been sought. One potential source of disruption of pregnancy is the exposure of pregnant women to toxic substances during the pregnancy. Of particular concern is the exposure of women in the very early periods of pregnancy. There has been a scarcity of animal studies suited to the study of toxic exposure in early pregnancy, to some extent because of the traditional view that preimplantation stages of development are refractory to the consequences of toxic insult. The general presumption that early stages are either killed or left unaffected to implant and develop normally has been shown to be an oversimplification. The blastocyst stage of development has, for example, been shown to be sensitive to cyclophosphamide,[20] heavy metals, and trypan blue.[21] Early embryos seem to exhibit differential sensitivity to treatment, dependent on specific developmental stage. For example, mouse embryos at the early blastocyst stage (day 3) are much more sensitive to the lethal effects of actinomycin D than at any of the other preimplantation stages. Actinomycin D prevents cleavage at these other preimplantation stages but does not cause cell death.[22] This differential sensitivity cannot be attributed to the rate or extent of drug accumulation since the less sensitive late blastocysts take up actinomycin D more rapidly and accumulate it more than do the more sensitive early blastocysts. Blastocysts are also more susceptible to the acute effects of methylmercury than morulae. Methylmercury exerts acute effects at high concentrations by arresting preimplantation development or by collapsing blastocysts, and at low concentrations it interferes with development of the inner cell mass.[23] Furthermore, methylnitrosourea will not prevent progression of morula stage embryos to the blastocyst stage at concentrations that cause blastocyst dysfunction.[24]

Within individual blastocysts, inner cell mass cells and trophectoderm may have different sensitivities to chemical insult. Adams et al.[25] administered various substances parenterally, including diethylstilbestrol, antimitotic agents, polyfunctional alkylating agents, and purine and pyrimidine analogues, to experimental animals during the preimplantation period of pregnancy and found that inner cell mass cells on the whole were more noticeably affected. This distinctive susceptibility of the inner cell mass and trophectoderm is presumably

the expression of differences in both type and rate of metabolic processes, whereby the more active and rapidly proliferating tissue of the embryo proper suffers adverse effects more readily. Alternatively, the difference in susceptibility between the two cell populations may reflect a difference in the recuperative potential (such as compensatory growth) of the two tissues.

The deleterious effects of preimplantation treatment range from increased intrauterine mortality to fetal growth retardation to actual malformations. For example, exposure to inhaled chloroform from days 1 to 7 significantly impaired the ability of female mice to maintain pregnancy but was not significantly teratogenic.[26] Mean fetal body weight and crown-rump length were decreased significantly among the surviving offspring. Intramuscular injection of nickel subsulfide to pregnant rats on day 6 of gestation also caused a significant increase in intrauterine mortality, although no skeletal or visceral anomalies were observed in pups in the treated or control litters.[27] Single intraperitoneal injections of nickel chloride to pregnant mice on day 1, 2, 3, 4, 5, or 6 of gestation resulted in decreased litter size, diminished fetal body weights, a larger frequency of both early and late resorptions, and an increased frequency of stillborn and abnormal fetuses, when compared with results in control groups.[28]

Takeuchi[29] found that single intraperitoneal injections of methylnitrosourea to mice on day 0, 1, 2, 3, or 4 of gestation resulted in no significant differences in the number of implantation sites between all the methylnitrosourea-treated groups and the control groups. However, the mean fetal death rates were significantly increased in methylnitrosourea-treated groups compared with the control groups, with early fetal deaths contributing substantially to these higher rates. The mean malformation rates were also significantly increased in groups treated with 10 mg/kg of methylnitrosourea on day 2, 3, or 4 as compared with the control groups. Exencephaly, cleft palate, and abnormal tail were prevalent malformations in each group. Cyproterone acetate treatment of pregnant mice[30] on day 2 resulted in a significant increase in rate of intrauterine mortality, exencephaly, and heart abnormalities, a dose-dependent increase in cleft palate and urinary tract abnormalities, and a concentration-dependent decrease in fetal weight. Medroxyprogesterone treatment on day 2 was followed by sporadic increases in dead and resorbed fetuses, a decrease in fetal weight, and an increase in the rates of cleft palate and malformed or abnormally developed fetuses.[30] Storeng and Jonsen[31] found a single intraperitoneal injection of ricin to mice on day 1, 2, or 3 of pregnancy had no significant effect on the implantation frequency and the number of live fetuses obtained from treated mothers. However, the number of abnormal fetuses in the ricin-treated groups exceeded that of the control groups, with exencephaly as one of the abnormalities observed. Exencephaly is believed to be induced by some toxic agents during the period of organogenesis, but Storeng and Jonsen hypothesize that the cases in this study may be due to an early effect of ricin on the preimplantation embryos with subsequent expression in later stages of fetal development.

Various mechanisms might be the cause of the deleterious effects of preimplantation treatment. Some chemicals may damage certain maternal tissues that are necessary for the maintenance of normal embryonic development; some chemicals may cause reduced maternal food intake; but in either case growth-retarded or malformed fetuses may result from damaged maternal functions. To test whether cyclophosphamide interferes predominantly with the development of the preimplantation embryo or with the decidualization of the uterus of the mother, rat embryos from treated mothers were transferred to untreated recipients and embryos from untreated mothers were transferred to pretreated foster mothers.[32] The results showed that when treated blastocysts were transferred to untreated mothers the overall implantation rate was not significantly different from that in the untreated, transferred control group. However, the percentage of live fetuses was significantly decreased and the resorption rate was significantly increased when compared with those of the control group. When untreated blastocysts were transferred to treated foster mothers, the implantation rate and the percentage of live fetuses were significantly decreased and the resorption rate was significantly increased when compared with that of the control group. The percentage of live fetuses was reduced to the same extent in both treated groups.

Inner cell mass cell sensitivity

The effect of chemical exposure in the preimplantation period does not appear to be simply a matter of inner cell mass cell death, particularly at sublethal concentrations of the offending agent. Snow and Tam[33] showed that the mouse embryo could be reduced to approximately 10% of its normal size after chemical exposure at a time when it was about to begin organogenesis, but it was nearly normal in size again before that phase of development was complete. Furthermore, much of the recovery in size was accomplished within 48 hours of the infliction of the damage. During this period of compensatory growth the embryo may be susceptible to irreversible morphogenetic damage. Moreover, the inner cell mass may contain as few as three or four cells that are fated to develop into the fetus.[34] Thus any significant cell death within this population should result in the complete disorganization of the embryo.

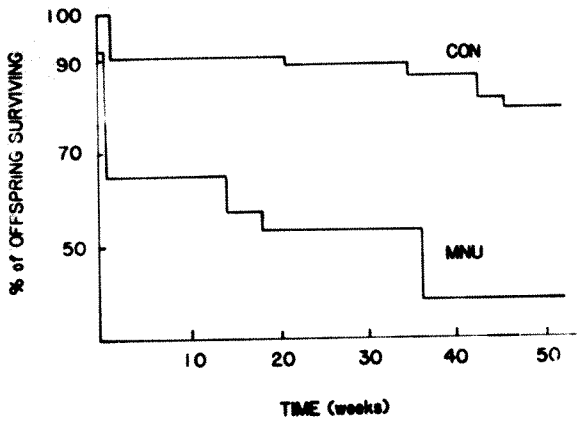

Fig. 2. Survival curves of offspring derived from embryos exposed to N-methyl-N-nitrosourea *(MNU)* or to the solvent dimethyl sulfoxide *(CON)*. The time after birth is shown in weeks. (n = 22 for *MNU;* n = 58 for *CON*). (Reprinted with permission of Cancer Research, Inc. From Iannaccone PM. Long-term affects of exposure to methylnitrosourea on blastocysts following transfer to surrogate female mice. Cancer Res 1984;44:2785-9.)

Combined in vitro, in vivo studies

Direct acting mutagens. Obviously, it is important to establish whether chemical exposures such as those discussed above have direct embryonic or fetal effects as opposed to maternal effects with subsequent poor pregnancy outcome. We have examined the issue of preimplantation sensitivity to chemical exposure with a combined in vitro, in vivo approach. In these experiments, embryos were removed from the uteri of pregnant mice at the blastocyst stage of development and exposed under precisely defined conditions in a dish. The embryos were then removed to the reproductive tract of pseudopregnant surrogate mothers. These experiments have included exposures to N-methyl-N-nitrosourea (methylnitrosourea) and the metabolites of benzo[a] pyrene. Methylnitrosourea is a direct-acting mutagen (that is, metabolism to an activated form is not required for mutagenesis) that alkylates large molecules including deoxyribonucleic acid. The manner in which this compound causes mutations is chemically analogous to the manner in which nicotine metabolites, the so-called tobacco-specific nitrosamines, cause mutations.[35, 36] Exposure to this chemical at concentrations well below lethal levels results in a dose-dependent decrease in the frequency of normal implantation without an effect on the total number of implantations (both normal and abnormal).[37] Blastocyst exposure to methylnitrosourea results in dose-dependent decreases in midgestational body length and an increase in the frequency of gross dysmorphogenesis at day 12 and day 15.[38] Exposure of gravida on day 3 (blastocyst stage in the mouse) results in malformations of fetuses in a dose-dependent manner assessed at day 18.[29] The malformations at each of the gestational points studied were related to growth retardation. When the exposed blastocysts were implanted in the uteri of surrogates that were then allowed to deliver their offspring, there was a profound dose-dependent decrease in the live birth rate. The offspring derived from the blastocysts that were exposed to methylnitrosourea had a threefold higher mortality rate than the offspring derived from solvent-exposed control blastocysts (Fig. 2).[24] These data strongly support the view that, with increasing sophistication of cellular coordination required to perform a function, the concentration of methylnitrosourea required to cause disruption of that function decreases. Since the EC_{50} (50% effective concentration; the concentration of methylnitrosourea that results in a 50% reduction in the test parameter) of methylnitrosourea for the immediate decrease in incorporation rates of precursors of macromolecular synthesis were similar to those for live birth rates,[24] it seems reasonable to presume that the effects of methylnitrosourea are immediate even if the manifestation of those effects may take place long after exposure (Table I). In aggregate these data suggest the possibility that blastocyst dysfunction is the result of subtle, nonlethal mutations that result in shifts in the developmental program of the embryo.

Table I. The 50% effective concentrations (EC_{50}) of methylnitrosourea

	EC_{50} (μg/ml)
Incorporation of:	
Tritium-labeled uridine	4.0,* 7.1†
Tritium-labeled thymidine	3.0,* 4.2† (4.2‡)
Tritium-labeled leucine	3.5*
Normal implantation	160†
Live birth	4.7

Modified from Iannaccone.[24]

*Incorporation rates determined at the end of a 1-hour exposure to methylnitrosourea.

†Incorporation rates determined 18 hours after a 1-hour exposure to methylnitrosourea.

‡Incorporation rates determined 18 hours after a 1-hour exposure of blastocysts without a zona pellucida to methylnitrosourea.

Indirect-acting mutagens. Similar embryonic dysfunction might be expected after exposure to indirect-acting mutagens (those that require metabolic activation in order to be mutagenic) if a relevant drug-metabolizing system capable of converting these chemicals to active metabolites were present in intimate contact with the developing embryo in the preimplantation period. Experiments were performed to determine if endometrial lining cells of the mouse uterus contain cytochrome P-450–dependent mixed function oxidase activity.[39] Cytochrome P-450 is known to be the enzyme system principally responsible for converting

stable polycyclic hydrocarbon procarcinogens to unstable electrophilic species capable of covalent interaction with deoxyribonucleic acid. The mouse uterine lining, consisting of both epithelial and stromal cells, is clearly a potential source of such enzymes. A number of stromal cell populations that are responsive to steroid hormones have been isolated.[40] Several cell strains have been isolated and are responsive to either estradiol and diethylstilbestrol or to progesterone. Other populations that are unresponsive to steroid hormones were isolated (Fig. 3). The progesterone-responsive cells can be growth inhibited by estrone or estriol. The cells contain inducible aryl hydrocarbon hydroxylase activity that catalyzes the conversion of benzo[a]pyrene to 3-hydroxy-benzo[a]pyrene and is one measure of cytochrome P-450 activity. Several clones of the endometrial stromal cell strains have been isolated in the presence or the absence of estradiol. These clones vary in response to estradiol with respect to cell growth.[40] Estradiol can reduce the basal and induced levels of aryl hydrocarbon hydroxylase activity when 2,3,7,8-tetrachlorodibenzo-p-dioxine is the inducer. The degree of induction of the activity by 2,3,7,8-tetrachlorodibenzo-p-dioxine is not afected by estradiol. The pattern of induction by benzanthracene in these clones is different.[40] The effect of hormone on aryl hydrocarbon hydroxylase induction by two different inducers implied that the inducers operate via separate mechanisms, presumably different aryl hydrocarbon receptors.[41, 42] This modulation of cytochrome P-450 activity by estrogen is associated with alterations in the pattern of microsomal proteins as revealed by denaturing sodium dodecyl sulfate–polyacrylamide gel electrophoresis. Electrophoresis has also shown that induction in the mouse liver occurs via different isozymes than induction in endometrium and that benzanthracene and 2,3,7,8-tetrachlorodibenzo-p-dioxine induce different forms of cytochrome P-450 in the endometrial cells. Additionally, there is a protein with a relative molecular weight of 52,400 that, while induced by benzanthracene in the absence of estradiol, is not induced in its presence. There are several possible explanations: that the induction of cytochrome P-450 activity by benzanthracene is altered in some cells by estrogen as the result of an interaction between their activated receptors, which results in a different pattern of isozyme induction; that the level of gene expression of the relevant forms of cytochrome P-450 is directly effected by estrogen; or that the induced protein(s) is(are) modified posttranscriptionally in the presence of estrogen. A similar result has been obtained for the induction of uterine aromatase that can be modified by the presence of steroid.[43]

Endometrial stromal cells possess the ability to convert benzo[a]pyrene to active metabolites, including

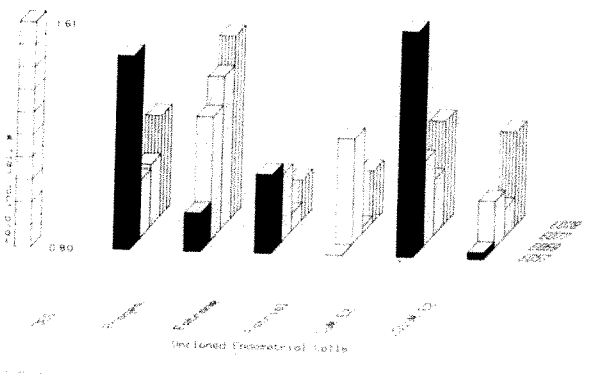

Fig. 3. Response of uncloned endometrial stromal cell strains to various steroids. The cell strain is shown on the z axis; the fold increase in cell number (in comparison to solvent-exposed cells) is shown on the y axis. Diethylstibestrol *(DES)*, progestrone *(Proges.)*, estrone, estriol, and 17β-estradiol *(E2)* were tested. (Reprinted with permission of Alan R. Liss, Inc. From Stols L, Iannaccone PM. Pattern of steroid interaction with inducers of aryl hydrocarbon hydroxylase activity in several cloned estradiol-responsive stromal cell strains from mouse endometrium. J Cell Physiol 1985;123:395-400.)

anti- and *syn*-benzo[a]pyrene-7,8-dihydrodiol 9,10-epoxides, which are capable of disrupting blastocyst functions in a concentration-dependent manner.[40] High-pressure liquid chromatography was used to demonstrate the site specificity of oxidation by cytochrome P-450 in microsomes isolated from estradiol-responsive mouse uterine cells.[40] Induced microsomes from mouse endometrial stromal cells were incubated with tritium-labeled benzo[a]pyrene and the metabolites were separated with high-pressure liquid chromatography. The resulting profiles demonstrated predominant oxidation at the 9,10 and 7,8 positions with no detectable 4,5 oxidation. These results support the conclusion that these cells are capable of generating benzo[a]pyrene-diol epoxides from benzo[a]pyrene-dihydrodiol. When microsomes from endometrial cells and blastocysts were incubated with benzo[a]pyrene-7,8-dihydrodiol for 1 hour, there were no morphologic effects, either immediately after exposure or 18 hours after exposure. This was true whether benzo[a]pyrene or the metabolite anti-benzo[a]pyrene-7,8-dihydrodiol 9,10-epoxide was used. Nevertheless, there was a concentration-dependent decrease in the frequency of total implantation and in the frequency of normal implantation rate, as well as in the number of animals that showed evidence of pregnancy when treated embryos were transferred to surrogate mothers. When embryos exposed in this manner were transferred to surrogates and allowed to come to term, a dose-dependent decrease in live birth rate was demonstrated.

The metabolite specificity of this effect was determined by exposing embryos to a racemic mixture

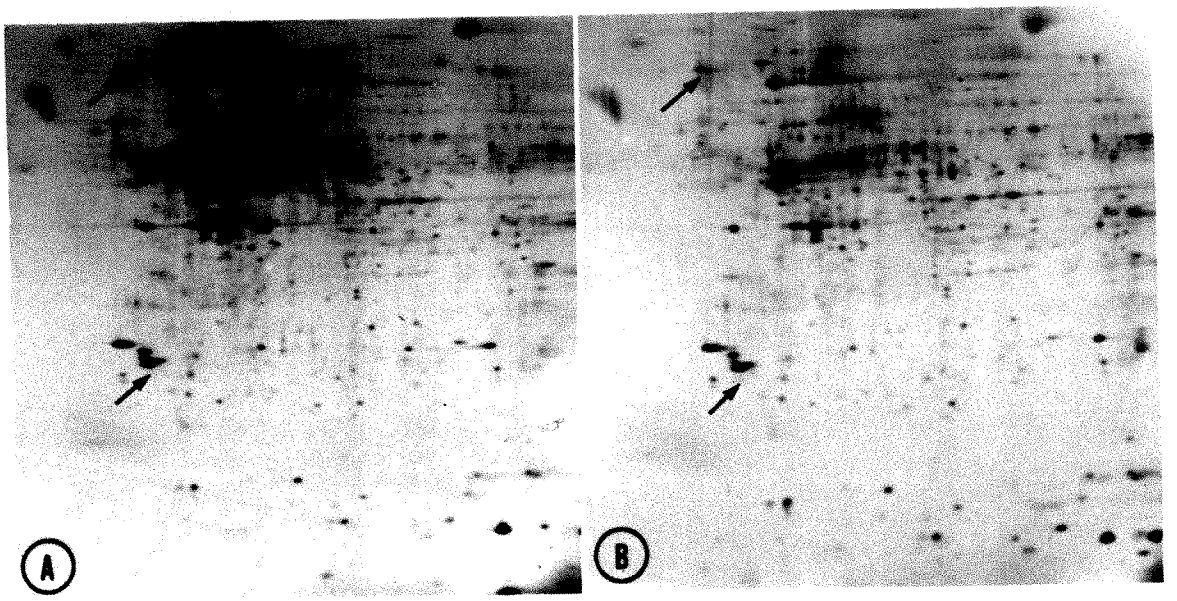

Fig. 4. Two-dimensional electrophoretogram of total protein from day 12 inbred mouse fetuses derived from blastocysts exposed in vitro to methylnitrosourea (10 μg/ml) with subsequent transfer to surrogate mothers. The second-dimension gels (shown here) have been silver stained and resolve approximately 900 spots. Panel *B* is from the fetus derived from methylnitrosourea-exposed blastocyst and Panel *A* is from the control (solvent-exposed) blastocyst. Two examples of protein alterations associated with treatment are illustrated *(arrows)*.

of *anti*-benzo[a]pyrene-7,8-dihydrodiol 9,10-epoxides. After insertion of embryos into the uteri of surrogates, there was a striking dose-dependent decrease in implantation rate and birth rate as well as a dose-dependent increase in the resorption rate. This particular metabolite is characterized by both cytotoxicity and mutagenicity in mammalian cells but not in bacteria. Similar experiments are being performed with *syn*-enantiomers, which are identical chemically except that the epoxide group is on the same side of the planar ring structure as the reference hydroxy-group. This difference, however, appears to profoundly decrease the mutagenicity of the metabolite while the cytotoxicity remains the same.[44]

Possible role of mutations

The possibility that induced mutation in the preimplantation period results in developmental dysfunction in the postimplantation period has been explored by attempts to identify altered proteins in very early organogenesis in the mouse. Embryos were exposed to two concentrations of methylnitrosourea at the blastocyst stage of development and reinserted into surrogate mothers. These pregnancies were interrupted at day 12, a time when organogenesis is just beginning in the mouse and maternal tissues can be critically separated from fetal tissues. The fetal tissues and fetal membranes were isolated and total protein preparations were subjected to two-dimensional electrophoresis (Fig. 4). The fetal tissues derived from methylnitrosourea-exposed blastocysts demonstrated a relatively small number of protein alterations. These alterations will be analyzed in an attempt to determine the role of mutagenesis in their formation as well as the role the alterations may play in poor pregnancy outcome.

It is clear that the coordinated expressions of the thousands of genes required to establish normal fetal development could not occur without orchestration by a relatively small set of supervisor or master genes. In *Drosophila* such genes have been identified and we now know that similar genes exist in mammalian species.[45-47] Whether these genes have the same function in Mammalia as they do in other animals remains to be established. We feel that the use of specific chemical disruption of embryonic function may serve as a valuable probe for the presence of such supervisor genes. Once the protein sequence of the altered protein is established, putative gene sequences can be deduced and used to define the presence and expression of the genes in normally developing fetal tissues.

The role of mutations in developmental defects can be addressed directly by analyzing insertional mutations that arise from the integration of exogenous deoxyribonucleic acid after pronuclear injection. Such transgenic animals have mutations wherever the exogenous deoxyribonucleic acid inserts in the host deoxyribonucleic acid. Occasionally, such a mutation occurs in a gene of developmental importance. If the transgenic animal is inbred to allow the expression of recessive phenotypes, then the role of the mutation in

the defect can be established. This has been accomplished in several instances. Insertional mutation of the α1(I) collagen gene results in disruption of blood vessel development and intrauterine death.[18] In the other example microinjection of deoxyribonucleic acid in pronuclear stage embryos resulted in a mutation of a gene that controls limb formation *(1d)*. Homozygous offspring of these animals suffer synostosis of the radius and the ulna, of the tibia and the fibia, as well as oligodactyly and syndactyly of digits in the forepaw and hindpaw.[19] Appropriate molecular probes are being used to sequence the genes responsible for these malformations.

In conclusion, broad advances in many other areas of biomedical research with attendant alleviation of human loss and suffering only serve to underscore our comparative inability to treat or even to understand birth defects and perinatal mortality. This must be due in large measure to our ignorance of the elegant mechanisms that organize and control fetal development in mammals. One can but hope that this situation will begin to change in the near future as new techniques are brought to bear on problems in reproductive biology.

SYMPOSIUM

Infection: A Complication of Obstetric and Gynecologic Surgery

F. Gary Cunningham, M.D., *Chairman*
Dallas, Texas

The following papers are based on selected presentations delivered at the symposium, "Infection: A Complication of Obstetric and Gynecologic Surgery," held at Napa, California, July 24-27, 1986.

Funds for the symposium were provided by an educational grant from Lederle Laboratories.

Treatment and prevention of female pelvic infection: The quest for single-agent therapy

F. Gary Cunningham, M.D.
Dallas, Texas

The advantages of a single-agent regimen for prevention or treatment of female pelvic infections are outlined, and the characteristics of an "ideal" single agent are described. Indications for antimicrobial use in obstetrics and gynecology as well as the pathogens most likely to cause infection are reviewed. Empirical treatment regimens are assessed not only for efficacy but also for safety, simplicity, cost, and potential for inducing bacterial resistance. Piperacillin, as an example of an antimicrobial that may be appropriate for single-agent use in female pelvic infections, is evaluated in depth. (AM J OBSTET GYNECOL 1987;157:485-8.)

Key words: Single-agent therapy, antimicrobial resistance, surgical infection

Female pelvic infections almost always involve anaerobes and aerobes that compose normal cervicovaginal flora. To ensure adequate antimicrobial coverage for all potential pathogens, standard therapy usually consists of two or more antibiotics given simultaneously. Although such conventional multiagent regimens have been able to eradicate most of these infections, the quest for a clinically effective single agent continues to be of primary interest. In fact, the attractiveness of such an antimicrobial has been significantly enhanced in recent years by considerations that include the cost of mixing and administering several drugs compared with the simplicity of a single-drug regimen.

The increased use of perioperative prophylaxis over the past 15 years has added new, and sometimes worrisome, dimensions to the problem of treating infection-related complications. The potential for inducing microbial resistance is integral to any decision regarding prophylactic antibiotic use. Thus ideal single-agent therapy would include minimal resistance induction.

Ideal single agent

The ideal single antibiotic for treatment and prevention of female pelvic infection must have a wide spectrum of in vitro activity inclusive of most major pathogenic bacteria likely to cause such infections. Moreover, the agent should have a well-studied and verified record in clinical practice. It should also have suitable tissue penetration at target sites most likely to be involved, such as pelvic abscesses. The ideal agent would have minimal potential for inducing bacterial resistance, thus making it useful for perioperative prophylaxis as well as for treatment. Finally, it should be safe and relatively inexpensive.

Piperacillin is a semisynthetic acylamino penicillin that has most of these characteristics and is used as monotherapy for treatment and prevention of female pelvic infection. In this symposium, we will review the clinical aspects of piperacillin vis-à-vis specific infections that we frequently prevent or treat, and we may conclude that it fulfills many requirements of an ideal agent for single-drug therapy.

Antimicrobial indications

Nonsurgical pelvic infection. By far, the most common indications for parenteral antimicrobial use in obstetrics and gynecology are pelvic infections that occur after operation. Nevertheless, we do encounter nonsurgical infections, the most common of which is acute, community-acquired salpingitis. These infections can be complicated by peritonitis and tuboovarian abscesses and frequently cause sterility. Other nonsurgical infections include perineal and Bartholin gland abscesses, which can be particularly dangerous in women with diabetes.

Surgical infections. Pelvic infections that occur after obstetric or gynecologic operations are most frequently encountered after cesarean section or abdominal or vaginal hysterectomy. Other surgical procedures, such as ovarian or tubal operations, are seldom complicated by infection and thus have not been extensively studied.

Prophylaxis. Although there are no rigid guidelines to define women who are candidates for perioperative prophylaxis, most infectious disease specialists agree that antimicrobials significantly reduce the rate of postoperative infection among women undergoing procedures known to be, or likely to be, contaminated. Specific indications for such prophylaxis in cesarean section or abdominal or vaginal hysterectomy will be addressed during this symposium.

Pathogens

Studies have shown that most female pelvic infections, surgical or nonsurgical, are caused by bacteria that compose the normal cervicovaginal flora. In 1977, for example, we reported a study of nearly 200 women with acute salpingitis and showed that the pathogens isolated from the peritoneal fluid taken from these women were identical to those found in women with postoperative obstetric and gynecologic infections.[1] Unlike surgical patients, these women apparently have a breach of the epithelial defenses caused by primary infection with pathogens that are not considered normal flora.

Sexually transmitted diseases: The exceptions. The most obvious exceptions with respect to the etiology of community-acquired salpingitis are the sexually transmitted pathogens *Neisseria gonorrhoeae, Chlamydia trachomatis,* and perhaps others. In our 1977 study, we found that about half of the cases were initiated by gonococcal infection, and Scandinavian investigators have subsequently concluded that nearly one third of cases of salpingitis are initiated by *C. trachomatis* infection. This incidence is probably similar in American women. However, in as many as half of women with salpingitis, initial infection with *N. gonorrhoeae* or *C. trachomatis* is followed by secondary infection with opportunistic organisms that compose the normal flora, and thus they are similar to postoperative infections.

Bacterial isolates. In general, bacteria most commonly isolated from women with pelvic infections are anaerobic streptococci (*Peptostreptococcus* and *Peptococcus* sp.), aerobic streptococci (group B streptococci and enterococci), coliforms (*Escherichia coli* and *Klebsiella*), *Bacteroides* sp. (*B. fragilis* and *B. bivius*), and *Clostridium* sp. Some of these deserve special mention.

Bacteroides. Approximately 10% to 20% of women with pelvic infections are infected with a member of the genus *Bacteroides (B. fragilis, B. bivius, B. melaninogenicus),* and this remains an important consideration for selecting an antimicrobial regimen for treatment. For perioperative prophylaxis, activity against *Bacteroides* and specifically *B. fragilis* appears less important.

We must continue to carefully monitor susceptibility of *B. fragilis* because of its pathogenicity and typical antimicrobial resistance. During the mid-1960s, for example, *Bacteroides*—a relatively "new" discovery at the time—was quite sensitive to the tetracyclines, but currently as many as 65% of isolates are resistant. Without in vitro susceptibility audits, however, we would have experienced 2 to 3 years of clinical failures and morbidity before arriving at the conclusion that, because of resistance by *Bacteroides,* tetracycline was no longer effective as empirical therapy for pelvic infection caused by these organisms.

Enterococci. After anaerobic streptococci, the pathogens most frequently isolated from women with pelvic infection at Parkland Hospital are aerobic streptococci. Particularly worrisome is that enterococci *(Streptococcus faecalis)* are isolated from nearly 25% of these women when cultures are taken from the uterus, amniotic fluid, or vaginal cuff. The pathogenicity of enterococci, which are generally considered low-virulence organisms, is still a matter of controversy. Nevertheless, since the organism is highly resistant to most currently used antimicrobials, a growing number of clinicians are intuitively concerned about providing coverage for it. Microbiologic trends indicate that enterococci are isolated more often than in previous decades, and there is concern that they may prove to be the emerging pathogens—the methicillin-resistant *Staphylococcus*—of the 1980 and 1990s.

Resistance

The problem of bacterial resistance to many potent antimicrobials is no longer theoretical and is a serious

threat to effective treatment of infection. Therapy for most surgical infections is empirical, and we seldom prescribe an antimicrobial on the basis of culture results. Audits of bacterial susceptibilities are crucial therefore to continuing successful empirical therapy by allowing detection of ecologic shifts and acquired resistance of bacterial strains to standard therapeutic regimens.

Resistance of *Bacteroides* has been reported with increasing frequency in recent years and is a problem of particular concern to those interested in obstetric and gynecologic infections. Cuchural et al.[2] examined patterns of resistance for 500 to 700 isolates each year for 1981 and 1982 and reported a rise in the incidence of resistance of *Bacteroides* strains to cefoxitin in vitro from 8% to 16%. This also reflects our experience with clinical isolates from women with post–cesarean section infections at Parkland Hospital.[3] There have been disturbing reports of in vitro resistance of *Bacteroides* to clindamycin, the "gold standard," as high as 10% in some centers since 1980.[4] Although clinical failures have not as yet reflected such in vitro resistance, it is imperative that we be aware of these trends to continue rational selection of empirical regimens.

In surgical prophylaxis, not only is existing bacterial resistance important but also there is concern about inducing resistance. Although it is uncertain whether such limited antimicrobial exposure induces significant resistance, antibiotic pressure in the form of numerous exposures definitely selects out nonsusceptible organisms. Another consideration is whether the drugs given for surgical prophylaxis induce β-lactamases that might render these agents useless in the future.

Empirical treatment regimens

Since treatment of female pelvic infections is largely empirical, antimicrobials used should be effective against the wide spectrum of potential pathogens. Although mild-to-moderate pelvic infections are frequently treated with a second-generation cephalosporin alone, serious infections are best treated with a "big gun" regimen. For clinical purposes, clindamycin plus an aminoglycoside remains the "gold standard" in terms of providing the best coverage for empirical treatment.[5] Although highly effective, this regimen has drawbacks that include toxicities associated with the aminoglycoside as well as costs of extra staff time required to administer and monitor two drugs. To avoid the side effects of aminoglycosides, some practitioners prefer clindamycin plus a cephalosporin. With this regimen, toxicity is less of a concern, but the expense of a two-drug regimen remains. Another highly effective regimen, used infrequently, is the combination of a cephalosporin or penicillin with chloramphenicol. Many feel that the rare possibility of chloramphenicol-induced aplastic anemia precludes its use. Finally, metronidazole, which has excellent in vitro activity against anaerobes, has been used in combination with an aminoglycoside or a penicillin; however, the clinical efficacy of such regimens has not been tested extensively.

Cefoxitin, a second-generation cephamycin, is frequently used as monotherapy for mild-to-moderate infection possibly caused by *B. fragilis*. As with other regimens, enterococci are not covered, but the consequences of this window in its spectrum are uncertain. Cefoxitin induces β-lactamases, which may be of clinical importance.

Piperacillin: single-agent therapy?

The suitability of any antimicrobial for single-agent therapy depends on how well it fulfills criteria previously outlined. Piperacillin is highly effective in vitro against both anaerobes and aerobes commonly isolated from female pelvic infections.[4] In a survey of 1140 mixed isolates from women undergoing hysterectomy at Parkland Hospital, Heard et al.[5] reported that piperacillin had the greatest in vitro activity of 13 drugs tested. An important exception to coverage obtained with piperacillin, as with all β-lactams, is lack of activity against *C. trachomatis*. This intracellular organism is associated with 30% to 50% of cases of acute salpingitis in the United States, and specific therapy with a tetracycline or erythromycin is used to eradicate it. A less important window with respect to antimicrobials given for pelvic infections is the lack of activity against coagulase-positive β-lactamase–producing staphylococci.

Enterococcal coverage. Since the pathogenicity of enterococci is controversial, the efficacy of piperacillin against these aerobic streptococci is currently a theoretical advantage. We continue to isolate these organisms from 25% of women with pelvic infections at Parkland, and in light of recent microbiologic trends, enterococcal coverage may prove to be a pragmatic, and crucial, advantage in the future.

Clinical efficacy. Piperacillin has been shown clinically effective in preliminary studies reported thus far. Since 1983, Sweet and Gilstrap and their colleagues[6,7] have reported on a total of 65 women with moderately severe pelvic infections that were treated with piperacillin. These were randomized studies and the comparative drugs were cefoxitin or clindamycin plus gentamicin. There was a 92% clinical success rate with piperacillin, and side effects were negligible. The results of other studies will be reported in this symposium.

β-Lactamase induction. Piperacillin is relatively resistant to most β-lactamases and does not readily induce microbial β-lactamase production. Thus bacterial resistance to piperacillin is less common than with "high inducers" of β-lactamases, such as some of the cephalosporins. Since perioperative antimicrobial prophylaxis is commonplace in numerous surgical procedures,

agents that do not induce bacterial resistance may be particularly valuable. Moreover, single-dose prophylaxis would intuitively lower the potential for resistance even further, and the efficacy of such regimens is being studied.

Safety. Piperacillin enjoys minimal toxicity common to all penicillins and can be used with confidence in nonallergic patients. Unlike aminoglycosides, piperacillin is not usually nephrotoxic and is not ototoxic.

Cost. There are several ways in which drug costs are assessed. The simplest is the basic cost of a drug itself, which, for piperacillin, is relatively low compared with the cost of some third-generation cephalosporins. Another way is to calculate staff costs for mixing, administering, and monitoring, and single-agent therapy is almost always less expensive than combination regimens. Finally, the risk and inherent costs of antibiotic failure can be high and can render low-priced but less effective regimens more expensive.

Single-agent therapy for women with acute polymicrobial pelvic infections

David L. Hemsell, M.D., Molly C. Heard, R.A., Brenda J. Nobles, and Patricia G. Hemsell, R.A.

Dallas, Texas

Pathogens that cause acute polymicrobial female pelvic infections usually do not differ from those that compose the normal flora of the lower reproductive tract. Accurate identification of these bacteria is difficult because cultures obtained via the lower tract can easily be contaminated. Although use of a double-lumen catheter-protected brush culture cannot completely eliminate the risk of contamination, it is the least invasive method for obtaining culture material from the upper reproductive tract. Compounding the problem of accurately identifying pathogens that cause acute upper tract infections is the fact that bacteria appear to be present in the upper tracts of asymptomatic women with normal examinations. Because of these problems and because of the polymicrobial nature of these infections, empiric therapy frequently includes more than one antimicrobial agent. Newer, semisynthetic penicillins and cephalosporins have expanded spectrums of in vitro activity against most of the bacteria frequently recovered from pelvic infection sites. Comparative clinical trials have shown these agents to be as effective when used alone as is combination therapy. With few exceptions, empiric monotherapy with one of these newer antimicrobials will be curative for women with acute upper tract infection, will have less potential toxicity, will require less space, materials, and manpower to administer, and will be less expensive. (AM J OBSTET GYNECOL 1987;157: 488-90.)

The normal flora of the lower reproductive tract has been described by numerous investigators.[1-5] It is from these bacteria that inoculation of a pelvic operative site occurs, resulting in hospital-acquired infection after hysterectomy or cesarean section. The same pathogens may be recovered from women with community-acquired infection. *Neisseria gonorrhoeae* is isolated from the majority of women treated in the United States for acute salpingitis. A significant problem for the obstetrician and gynecologist is how to accurately culture the infected pelvic site. Modification of a bronchial double-lumen catheter brush device now allows culture of the endometrium with little, if any, contamination by lower reproductive tract flora.[6] It is much more difficult to culture the infection site in women who develop a pelvic infection after hysterectomy because the infection is usually cephalad and lateral to the vaginal surgical margin. When an accurate culture is performed, it is not uncommon to recover a mixture of three to nine aerobic and anaerobic gram-positive and gram-negative bacteria from infection sites, compounding the problem of accurately identifying the true pathogen. Although blood cultures are quite accurate, most are sterile prior to treatment for acute pelvic infection.

Upper tract flora

Ongoing research in our institution indicating that there may be a "normal flora" in the upper reproductive tract may further compound the problem of accurately identifying pathogens in women with acute community-acquired pelvic infection. Women recently admitted for treatment of acute pelvic inflammatory disease had endometrial cultures performed with the protected-brush device prior to treatment as well as when they attended the clinic 4 to 14 days after therapy. Even though they were afebrile, asymptomatic, and had a normal pelvic examination, a mean of more than three bacteria was recovered from protected endometrial cultures. Gram-positive aerobes and gram-positive and gram-negative anaerobes including *Bacteroides fragilis* were recovered, as was *Chlamydia trachomatis* (unpublished data). Those unsuspected results stimulated similar evaluations in consenting asymptomatic women with normal pelvic examinations who were attending our family planning clinics for annual examinations. None had a history of prior acute pelvic inflammatory disease. A mean of more than four bacteria was recovered from 36 women for whom such data are available. This appeared to confirm the hypothesis that an upper reproductive tract flora may exist. Peritoneal fluid from asymptomatic women undergoing elective tubal sterilization has been cultured and found to contain bacteria.[7]

Combination therapy

The polymicrobial nature of acute pelvic infections has been thoroughly elucidated.[8-11] As a result, combination antimicrobial therapy was usually used for initial empirical therapy of such infections. Penicillin, for example, was usually combined with an aminoglycoside or tetracycline, with an efficacy of 70% to 80%. Results with such regimens were similar in our hospital.[12] An anaerobic-specific antimicrobial such as clindamycin or chloramphenicol was not included initially because of the potential toxicity associated with these agents. Since a third antibiotic was required in 20% to 30% of cases, and since a significant number of anaerobes was recovered from cultures taken from pelvic infection sites, a decision was made to evaluate anaerobic-specific antimicrobials as part of initial therapy. Efficacy with clindamycin/gentamicin was 95% compared with only 71% for penicillin/gentamicin, clearly indicating a need to include predictable antianaerobic activity as part of initial therapy.[13] Both clindamycin and metronidazole have been combined with an aminoglycoside and are associated with efficacy of 95% or better.[14]

Many obstetricians and gynecologists administered ampicillin as initial therapy for pelvic infections and continue to do so with success (~95% efficacy). If such is the case, alteration in therapeutic regimen is not indicated. However, if the result is comparable with the 81% efficacy rate reported by Sorrell et al.,[15] altering the therapeutic regimen should be considered to achieve and maintain efficacy in the mid-90% range. Newer semisynthetic penicillins have an expanded spectrum that includes bactericidal activity against gram-positive and gram-negative aerobic and anaerobic bacteria.[15-17] The same is true for expanded-spectrum cephalosporins.[16, 13-20]

Aminoglycosides

With the development of synthetic antimicrobials that demonstrate in vitro activity against a wide range of gram-positive and gram-negative aerobic and anaerobic bacteria and that are as effective clinically as combination therapy, the necessity for combination therapy becomes less clear. Most combination regimens include an aminoglycoside. The predominant gram-negative aerobic pathogen in pelvic infections is *Escherichia coli*. Although *E. coli* and other Enterobacteriaceae recovered from women with acute pelvic infection are usually exquisitely sensitive to aminoglycosides, they are also sensitive to many of the newer penicillins and cephalosporins. The therapeutic range for gentamicin falls between peak concentrations of 5.0 and 8.0 μg/ml and trough concentrations of 0.5 and 1.8 μg/ml at an 8-hour dosing interval. Renal toxicity and ototoxicity occur in 3% to 10% of patients treated with aminoglycosides and usually occur when peak concentrations are >12 to 15 μg/ml and trough concentrations exceed 2 μg/ml. To make these determinations, repeated serum gentamicin concentrations must be performed. Since each such determination costs approximately $30, using serum concentrations to adjust dos-

age can contribute significantly to higher or increased health care costs. If such precision therapy is required to eradicate a pathogen sensitive only to aminoglycosides, the cost would certainly be justified. Fortunately, however, such a situation is rare in acute pelvic infections.

The recommended gentamicin dose for patients with severe infections is 3.5 mg/kg/day and is increased to 5 mg/kg/day in life-threatening infections. Zaske et al.[21, 22] have determined the pharmacodynamics of gentamicin in both obstetric and gynecologic patients and reported that the dose required for the treatment of such patients with acute pelvic infection ranges from 1.9 to 14.0 mg/kg/day. In obstetric patients and gynecologic patients, respectively, mean doses of 5.2 and 5.1 mg/kg/day were required to maintain the concentration of gentamicin within a therapeutic range. Forty-seven percent of the women required more than 5 mg/kg/day to maintain therapeutic concentrations. It was also learned that approximately 75% of patients required a 6-hour—not an 8-hour—dosing interval. Thus combination therapy that includes an aminoglycoside is more costly, is potentially more toxic, requires monitoring, and requires more man hours to accomplish.

Single-agent therapy

The primary concern of the physician treating a woman with an acute polymicrobial soft tissue pelvic infection obviously is curing the infection. If various regimens are therapeutically equivalent, the potential for toxicity or adverse reaction should be the next consideration. Finally, if regimens are relatively equivalent with respect to efficacy and safety, cost becomes the important consideration. Regimens combining several therapeutic agents are occasionally necessary in the treatment of the woman with an acute pelvic infection but should demonstrate superior efficacy to justify the risks of adverse reactions and the increased costs of drug, storage space, and manpower associated with their use. Such justification exists in infections in which a potential pathogen is identified against which the single-agent regimen is ineffective, such as *C. trachomatis* in a woman with acute salpingitis. Large tuboovarian or pelvic abscesses are in another category of infection for which combination therapy is appropriate. Single-agent therapy with newer expanded-spectrum penicillins and cephalosporins has been repeatedly shown to be equally as effective as combination therapy for most types of pelvic infection.

Changing concepts in obstetric antibiotic prophylaxis

Rudolph P. Galask, M.D.
Iowa City, Iowa

The evolution of antibiotic prophylaxis in cesarean section is traced from the discovery of sulfa compounds in the 1940s to the present. Prolonged courses of antibiotics, initiated before the surgical incision, have given way to shorter, three-dose and even single-dose regimens administered after clamping of the umbilical cord. Several factors have been proposed to help identify patients at greatest risk of infection. Guidelines for antibiotic prophylaxis are reviewed. The effects of antibiotics on host flora are described, and the implications of bacterial resistance for selection of a prophylactic agent, particularly with respect to induction of the Richmond-Sykes type I β-lactamase enzyme, are discussed. (Am J Obstet Gynecol 1987;157:491-7.)

Key words: Perioperative antibiotic prophylaxis, β-lactamase enzymes

A major challenge for physicians dealing with parturients has been the potential occurrence of serious infections during the postpartum period. The incidence of infection is of even greater concern for those patients who undergo an operative delivery. Because of these issues, early attempts to decrease the incidence of infections with prophylactic antibiotics were reported soon after effective drugs were discovered. In 1943, Richards,[1] for example, reported that the use of sulfa compounds decreased morbidity. Hesseltine and Thelen,[2] however, using local applications of sulfas under the bladder flap in 1948, did not appreciably reduce the infection rate and suggested that local prophylaxis of this type would result in a marked increase in adhesions at the time of a subsequent operation. They concluded therefore that the use of these compounds was not beneficial to their patients. Keettel and Plass[3] studied the use of intramuscular penicillin given to 382 women delivered vaginally and compared the incidence of infections in this group with that in 391 untreated control patients. They reported infection rates of 6.4% in the control group and 1.3% in the treated group and observed that the number of gram-positive organisms decreased while the gram-negative organisms increased in the treated group when compared with the control group. Although a lower incidence of infections in the treated patients was demonstrated, Keettel and Plass concluded that the penicillins might be more useful as prophylaxis in patients requiring a cesarean section. They did not, however, study that population.

Because of questions regarding the possible development of microbial resistance, the use of prophylactically administered antibiotics was not well accepted in obstetric practice during the 1950s and 1960s. Indeed the efficacy of antibiotic prophylaxis remained controversial among all of the surgical specialties. In a paper presented at the Twenty-second Annual Meeting of the Society of University Surgeons, Burke[4] reported results of a study that delineated a specific period during which antibiotic action could effectively prevent staphylococcal wound infections in an experimental animal model. He was able to show that if an antibiotic was given at any time from 1 hour prior to the inoculation of organisms up to 3 hours after the insult, a significant reduction in wound size occurred. This study, which was later published, established the currently recognized principle on which effective use of antibiotic prophylaxis is based, namely, that adequate levels of the antimicrobial agent must be in the tissue at the time of contamination.

During the 1970s, several changes in the practice of obstetrics increased our understanding of peripartum complications, particularly those involving sepsis. Improved microbiologic techniques, especially methods to isolate and identify anaerobic microorganisms, led to a clearer perception of the mechanisms of abscess formation. Obstetricians interested in infectious disease began to recognize the role of the indigenous microflora as the "contaminants" that caused the majority of postoperative infectious complications. Moreover, for a variety of reasons, the number of cesarean sections being performed was markedly increasing.[5] All of these factors contributed to the sense that the incidence of infection-related complications was unacceptably high and provided the impetus for the use of perioperative antibiotic administration in obstetrics.

Evolution of prophylactic regimens

Reports of sepsis in more than 60% of patients untreated after cesarean section compared with significantly fewer postoperative infections in treated patients

From the Department of Obstetrics and Gynecology, The University of Iowa College of Medicine.

prompted a number of obstetrician investigators to recommend the use of antibiotic prophylaxis for patients undergoing this procedure.[6-10] Early studies used a prolonged regimen consisting of an initial dose prior to the incision followed by 3 to 5 days of antibiotic therapy.[5, 11-13] Fortunately, several investigators recognized early that such regimens were therapeutic rather than prophylactic and recommended shorter, 1-day, three-dose courses beginning prior to the procedure and followed by only two subsequent doses of drug. A major advance in obstetric prophylaxis was reported by Gordon et al.[14] when they showed that the administration of ampicillin *after* the umbilical cord was clamped was as effective as giving the drug prior to the operative delivery procedure. This logical finding, which agreed with Burke's previous work, eliminated the possibility of placental transfer of antibiotic to the fetus. Since a number of other reports confirmed that delaying administration of the antibiotic until termination of blood flow to the infant was as effective for prophylaxis as preoperative administration, the majority of obstetricians have accepted this practice. The use of multiple doses of antibiotic to the mother during the first postoperative day was, however, continued. In 1983, Hawrylyshyn et al.[15] reported a significant decrease in postoperative infections after a single, 2 gm dose of cefoxitin given at the time the umbilical cord was clamped. Even though this important finding has been confirmed by others, single-dose prophylaxis has not been universally adopted.[16-18]

Identifying patients at risk

Unfortunately, early studies included all patients undergoing cesarean section and did not identify the infectious sites that were responsible for the reported morbidity. When a number of investigators became concerned about the indiscriminate use of antibiotics in all patients, attempts were made to identify those patients who were at greatest risk and who would obtain the greatest benefit.

Gibbs and Weinstein[19] were the first investigators to report data regarding the risk of infection in their patient population. They found that at their institution, regardless of whether patients were undergoing primary or repeat cesarean section, the risk of infection when antibiotics were not used was high. Johnson et al.,[20] on the other hand, found that patients undergoing elective repeat cesarean section were at low risk of developing infections and did not benefit from antibiotic prophylaxis. Phelan and Pruyn[21] also reported that the risk of infection was greatest in those patients undergoing primary cesarean sections and that the use of an antibiotic resulted in substantially improved outcomes. Further refinements regarding the patient population at risk were reported by Rothbard et al.,[22] who demonstrated that women in labor prior to the procedure were at greater risk than those who were not in labor at the time of primary cesarean section. Others have reported similar findings.[10, 13, 14, 23]

In an attempt to further define the factors that place patients at risk for postoperative sepsis, Green et al.[8] analyzed 15 variables and showed that anemia and a general anesthetic, as well as labor, were risk factors in their patients. Other investigators have reported that ruptured membranes[10] and internal fetal monitoring[9] can also be considered factors that increase the risk of infection. The identification of the patient population at risk, as well as the various events that might predispose otherwise normal individuals to a septic postoperative course, is extremely important. If one could reasonably predict and selectively administer antibiotic prophylaxis only to the high-risk population, the majority of patients would be spared the potential consequences of an unnecessary drug. At present, it appears that women in labor with ruptured membranes who are undergoing a primary cesarean section are at risk of infection. The importance of such variables as low socioeconomic status, obesity, anemia, internal fetal monitoring, type of anesthesia, and blood loss as predisposing factors appears to vary from report to report. Therefore the significance of any or all of these confounding variables must be individualized and considered along with the infection rate at a given institution.

Selecting an agent

Since 1968, when Miller and Crichton[6] reported that ampicillin prophylaxis was effective in decreasing postoperative infections, an increasing number of drugs has been added to the list. In fact, to date, penicillin, ampicillin, carbenicillin, ticarcillin, piperacillin, cephalothin, cephaloridine, cefazolin, cefamandole, cefoxitin, cephradine, cefoperazone, cefotaxime, moxalactam, cefotetan, kanamycin, gentamicin, clindamycin, metronidazole, and sulfamethoxazole-trimethoprim have been used for surgical prophylaxis, and all have demonstrated efficacy either alone or in combination with another compound. The difficulty in comparing drug efficacies is that these studies varied with respect to patient populations, time, duration, route of administration, and morbidity criteria, as well as major bias potential due to lack of prospective blinding of the subjects and controls. Nevertheless, when one considers the studies as a whole and disregards variations in design, it appears that perioperative antibiotics significantly decrease the incidence of postoperative infection.

The question that remains therefore is not whether to use an agent for prophylaxis but rather which agent to use. Ledger et al.[24] published a proposed list of guidelines, which were subsequently revised and restated by

Johnson et al.,[20] on selecting a drug for perioperative administration: (1) The procedure must have a significant postoperative infectious morbidity or the patient must be thought to have an altered host response to infection. (2) The operative procedure must be associated with a high probability of microbial contamination. (3) The drug must be of low toxicity, must have an established record of patient safety, and must not be routinely used for serious infections. (4) The drug used must have a spectrum of activity that includes those microorganisms from the site of contamination that are most likely to cause infection. (5) The drug must achieve a reasonable tissue concentration during the procedure and be administered for a short duration. (6) The hospital must have a functioning infection surveillance program with established guidelines and maintain records of current antibiotic susceptibility patterns prior to initiating elective antibiotic prophylaxis for general use.

Although meant as guidelines, these tenets constitute a practical basis for establishing need for prophylaxis and provide the preliminary structure necessary to proceed in a given hospital or practice. Nevertheless, considering the overwhelming number of effective drugs available, the choice of antibiotic remains problematic.

The aminoglycosides, because of their potential ototoxicity and nephrotoxicity and because they require a second drug to provide adequate coverage, should not be considered for prophylaxis. Similarly, because of their potential maternal hepatotoxicity, the tetracyclines are not suited for this purpose. Of the remaining classes of antibiotics, the penicillins and cephalosporin-related antibiotics seem the best choices for prophylactic use in surgical delivery. These β-lactam antibiotics have been well studied in both gynecology and obstetrics and have been shown to effectively reduce the incidence of postoperative infection when administered prophylactically during the perioperative period. The previously stated guidelines can be helpful for selecting an agent since they suggest using a relatively inexpensive drug that is not used as therapy for serious infections. Although this appears simplistic, it must be understood that a drug chosen for prophylaxis should be one that is not used for nosocomial infections, including postoperative sepsis in a patient who received it for prophylaxis since resistance to it may have already developed.

For almost 20 years, we have recognized that, in general, any antibiotic given either prior to or early in the procedure (when umbilical blood flow has been terminated) will result in decreased maternal infection. Extrapolating from the most recent studies, it appears, moreover, that the duration of adequate drug levels in the tissues need not be prolonged. Therefore most drugs with a reasonable half-life (1 to 2 hours) should be as effective when given as a single dose as when given in multiple doses. Since numerous drugs with varying spectrums of antimicrobial activity have been studied, it is apparent that activity against all of the organisms present in the cervicovaginal flora is unnecessary. Although these organisms are frequently isolated from post–cesarean section infections, simply decreasing their concentration (rather than eradicating them) appears to be effective in reducing infection.

The appearance of resistance

It would seem that any antibiotic with a reasonable half-life and spectrum of activity that is both nontoxic and inexpensive would be an ideal candidate for prophylactic "drug of choice." However, just as we have become more sophisticated with respect to perinatology, we have also begun to understand the wider implications of our drug choices. Selective pressure by frequent use of antibiotics has already altered the effectiveness of some of our most well-accepted regimens. In many hospitals, for example, the majority of coliforms, for example, *Escherichia coli,* have become resistant to ampicillin. Although this type of selection pressure leading to bacterial resistance has been a concern of infectious disease specialists since antibiotic prophylaxis came into vogue, a direct cause and effect has been difficult to demonstrate. Nevertheless, Moellering and Wennersten,[25] using computer analysis, were able to show that an increase in the prevalence of infections due to gentamicin-resistant organisms coincided with increased use of the drug at the Massachusetts General Hospital.

Effects of antibiotics on host flora

The effect of an antibiotic on host flora has been evaluated by several investigators in patients undergoing cesarean section. Gibbs and Weinstein,[19] for example, isolated enterococci and *E. coli* from endometrial cultures up to 5 days after the procedure in subjects who received a combination of clindamycin plus gentamicin. In previously unpublished work, Ohm-Smith and Galask studied 38 women who had been scheduled to have an elective repeat cesarean section and who had been randomly assigned to receive either a cephalosporin or a placebo according to a double-blind protocol. Cultures were obtained in 34 of the 38 subjects both before operation and on the fourth or fifth postoperative day, 1 to 2 days after the study medication had been discontinued. Table I shows that, although the average number of aerobic and anaerobic organisms was similar in the two groups when the preoperative cultures were evaluated, an increased number of anaerobic organisms was seen in the postoperative placebo group. Fig. 1 shows that there was a marked increase in the percent of cultures positive for

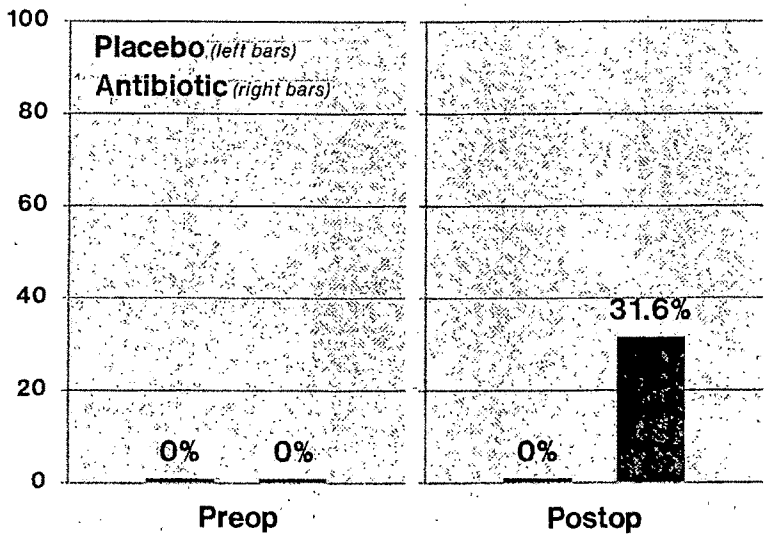

Fig. 1. Percent of cultures positive for cephalosporin-resistant gram-negative rods.

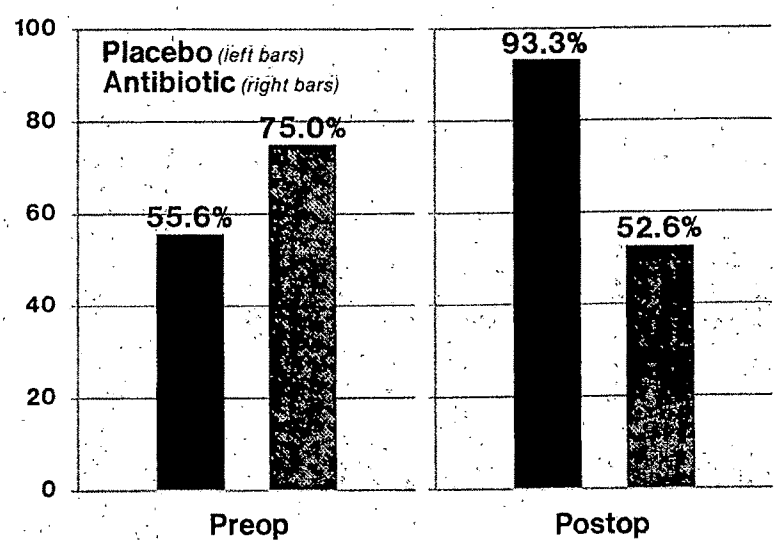

Fig. 2. Percent of cultures positive for anaerobic gram-negative rods.

Table I. Average number of different organisms per culture

Patient group and type of organism	*Preoperative cultures*	*Postoperative cultures*
Placebo		
Aerobic	2.5	3.1
Anaerobic	4.2	2.3
Antibiotic		
Aerobic	2.6	2.3
Anaerobic	4.5	2.7

cephalosporin-resistant gram-negative rods only in the treated group. Fig. 2 shows that there was an increase in percent of cultures positive for anaerobic gram-negative rods in the placebo group compared with a slight decrease in the treated group. Of greater clinical importance, however, were the marked increases in percent of cultures positive for both *Bacteroides asaccharolyticus* (Fig. 3) and *B. bivius* (Fig. 4) in the placebo group. *B. fragilis* and *B. distasonis* were also isolated with slightly greater frequency in the placebo group.

The results are disconcerting since they suggest that cervicovaginal flora can be affected, regardless of whether an antibiotic is used. Although no untoward problems with resistant organisms were noted in this or other studies, the effects of antibiotic selection remain apparent. Interestingly, a recent report by Ganesh et al.[18] suggests that trimethoprim-sulfamethoxazole lowered morbidity with a lesser effect on the flora. Further studies will be required to confirm this finding. An antibiotic that can decrease morbidity with minimal al-

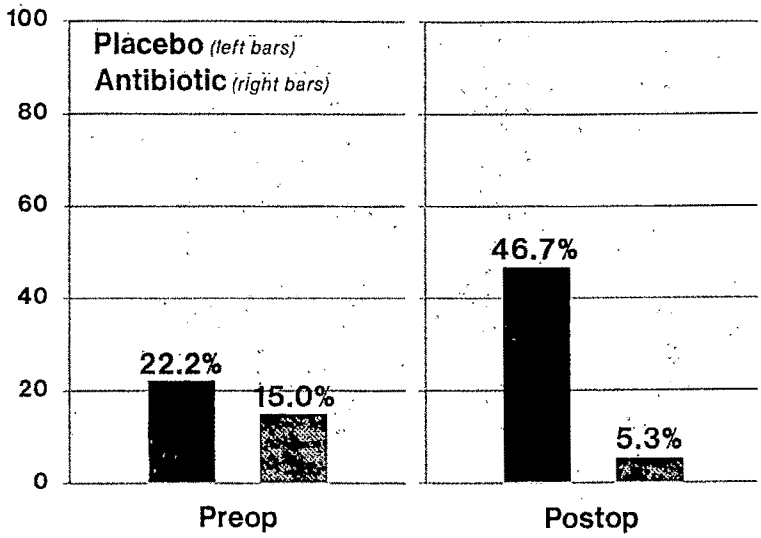

Fig. 3. Percent of cultures positive for *B. asaccharolyticus.*

teration of the flora would be an excellent choice for prophylaxis, provided that the agent is nontoxic and inexpensive.

β-Lactamase induction

Concern about the development of microbial resistance resulting from indiscriminate use of perioperative antibiotics for prophylaxis has not previously been justified. Recent evidence suggests, however, that a certain type of bacterial resistance to the β-lactam antibiotics may be important when one is selecting drugs for prophylaxis. As generations of β-lactamase–resistant antibiotics were developed and released, it was believed that there would be a proportional rise in efficacy. Although improvements in our antibiotic armamentarium have succeeded in decreasing the use of combinations of two or three different drugs, disturbing reports in the literature have suggested that certain microorganisms rapidly developed resistance to these newer agents. Perhaps even more distressing is the possibility that current in vitro susceptibility testing may be inadequate to detect this type of antibiotic resistance when it occurs. Unlike resistance that could be explained by bacterial tolerance to the lytic effects of β-lactam antibiotics, which has been described in the past and recently reviewed,[26] it appears that a different type of resistance to the β-lactam antibiotics is occurring, the significance of which previously was not rec-

ognized. This resistance is due to the induction of a specific type of β-lactamase enzyme of the Richmond-Sykes type I group.[27] It has been suggested that these cephalosporinases are produced by the derepression of a control gene on the bacterial chromosome and not by a transferable plasmid.[28] Although resistance is not transferred to other strains, certain gram-negative enteric bacteria (mutant and wild-type organisms) can become resistant to the newer cephalosporins previously thought to be stable to the effects of β-lactamase enzymes. More interesting is the fact that with this type of resistance, the β-lactam ring does not undergo classic hydrolysis; rather, a stable complex is formed between the antibiotic and the enzyme.[29] The newer, relatively β-lactamase–stable cephalosporins that bind to the penicillin-binding proteins types I and III are affected the most. When present, the enzyme confers simultaneous resistance to most of the broad- and extended-spectrum penicillins, as well as to the second- and third-generation cephalosporins, including the cephamycins and the newer monobactams.

This Richmond-Sykes type I β-lactamase enzyme exerts its action within the periplasmic space of the induced organism. Antibiotics gain access to this space by transversing the outer membrane of the bacterium through protein channels called porins. Once inside the periplasmic space, an antibiotic must reach and bind to a specific type of protein-binding protein to affect cell wall synthesis. Classically, a β-lactamase produced by the cell binds to an antibiotic molecule, hydrolyzes the β-lactam ring, releases the inactive compound, and binds to another molecule. When sufficient enzyme-to-antibiotic concentrations are present, the organism is protected from the effects of the drug. It appears, however, that the resistance conferred by the Richmond-Sykes type I enzyme does not follow this classic pathway. When an organism has been induced (derepressed), it produces large quantities of enzyme, which bind to the newer, stable antibiotics and do not hydrolyze the molecules but remain bound to them, blocking their ability to attach to their specific penicillin-binding proteins. This blocking or trapping effect protects the organism and can develop during therapy for an infectious disease. Further, this type of resistance is generally undetected because of the low inoculum size (approximately 10^4), and thus insufficient number of organisms, used by commercial and hospital laboratories for antibiotic susceptibility testing. This is a clinically important point since it helps to explain antibiotic failure in a patient who is being treated with a reportedly effective drug.

We now recognize that certain of the newer β-lactam antibiotics can act as inducers of this class of β-lactamase enzymes. Clearly, if an antibiotic used perioperatively to prevent infection causes enzyme induction and the patient subsequently becomes infected, a number of the organisms present at the site would be resistant to most of the antibiotics logically used to treat the disease process. Thus it would be prudent not to use a drug for prophylaxis that has been shown to be associated with the production of inducible, nonhydrolytic enzymes. Apparently, the most potent inducers of this type of resistance are the newer β-lactamase–stable second- and third-generation cephalosporins. Cefoxitin, for example, has been reported to induce resistance to a number of cephalosporins as well as to the new, extended-spectrum penicillins.[30] It is fortunate that the organisms in which this resistance is most likely to occur—enteric bacteria such as *Enterobacter cloacae*[31]—are not frequently encountered in postoperative obstetric infections.

Comment

Clearly, advances have been made in our understanding and use of antibiotic prophylaxis in obstetrics. The efficacy of perioperative antibiotic administration in decreasing the incidence of serious infections has been demonstrated and accepted. We have been able to identify patients who are at high risk and benefit most from prophylaxis. The amount of drug administered to each patient has decreased. The practice of delaying antibiotic administration until the umbilical cord is clamped to protect the neonate has been widely accepted.

It is also apparent, however, that our understanding of the effects of perioperative antibiotic prophylaxis is still incomplete. Single-dose prophylaxis, which would further decrease the amount of drug received by the patient, has yet to be established as the accepted regimen. The identification of antibiotics or chemotherapeutics that would decrease morbidity while not markedly affecting the indigenous flora is only beginning. Certainly, the implications of inducible antibiotic resistance by certain drugs are vitally important and must be thoroughly evaluated. It seems that we have raised as many questions as we have answered and may still be as far from finding the ideal drug for prophylaxis as Ehrlich was in his search for a "Silver Bullet."

Single-dose prophylaxis for vaginal and abdominal hysterectomy

David L. Hemsell, M.D., Molly C. Heard, R.A., Brenda J. Nobles, Roger E. Bawdon, Ph.D., and Patricia G. Hemsell, R.A.
Dallas, Texas

The practice of administering perioperative antimicrobials to uninfected patients undergoing elective surgical procedures has been subjected to careful prospective investigative scrutiny during the past two decades. A wound classification system was developed, helping to identify procedures for which prophylaxis did not provide benefit to the patient. Guidelines for prophylaxis in hysterectomy were proposed and risk factors were sought. Pharmacokinetics and spectrum of antibacterial activity, although variables of paramount importance in predicting success in the treatment of established infections, were discovered to have questionable impact on prophylactic efficacy. Duration of antimicrobial administration has gradually diminished from the total length of hospital stay to a single preoperative dose without increased risk of infection; efficacy may be related to route of administration. The wisdom of using newer agents for prophylaxis is addressed and questioned. (Am J Obstet Gynecol 1987;157:498-501.)

Key words: Surgical prophylaxis, vaginal/abdominal hysterectomy

Antimicrobial administration to prevent infection after most elective surgical procedures, including hysterectomy, was popularized in the early 1950s. By the mid to late 1950s, it was a common practice to begin administering antimicrobials to patients scheduled for any surgical procedure from the time they were admitted to the hospital until they went home some 8 to 10 days later. Very few, if any, controlled studies delineating the benefits and risks of such a practice had been done at that time.

Specialists in internal medicine warned of the potential hazards of prolonged antimicrobial administration in noninfected persons, but their warnings went unheeded. Some patients undergoing primarily orthopedic and neurosurgical procedures developed superinfections as a result of such antimicrobial regimens. The serious sequelae and even deaths associated with these superinfections eventually led to radical changes in the approach to surgical prophylaxis.

Prospective studies were conducted in all surgical subspecialties to identify those surgical procedures for which the prophylactic administration of antimicrobials was beneficial. The first articles reporting the results of these studies began to appear in the gynecologic literature in the late 1960s[1] and have continued to appear since that time.

Surgical classifications

The recent proliferation of newer antimicrobials has accentuated the importance of applying the 1975 guidelines of Ledger et al.[2] for surgical prophylaxis.

Hysterectomy was originally designated as a "clean" procedure because the postoperative infection rate, particularly of abdominal hysterectomy, was so low.[3] Hysterectomy has since appropriately been reclassified as a clean/contaminated surgical procedure because it is performed in an area containing significant potential pathogens as part of the normal flora. Host defense mechanisms are paramount in the prevention of infection after elective hysterectomy. Since host defense mechanisms are impaired in debilitated and/or immunodeficient patients, these women are at increased risk for infection after hysterectomy or after any other surgical procedure. Low socioeconomic status is another, relatively universal risk factor for increased postoperative infection. Even with an intact immune system, an operative site grossly contaminated with a substantial inoculum will also usually result in postoperative infection.

Applying the principles of good surgical technique is also important in decreasing the incidence of postoperative infection. In addition to asepsis in the operating room, which is standard practice, many surgeons advocate douching the evening before and the morning of hysterectomy. Since serum and blood provide an ideal medium for the growth of bacteria that compose the normal flora of the lower reproductive tract (which are inoculated into the operative site), adequate hemostasis and closing of dead space are imperative. Creating small pedicles and gentle handling

of tissues diminish the volume of necrotic tissue that might also provide a nidus for subsequent infection.

Bacterial isolates

A total of 2298 gram-positive and gram-negative aerobic and anaerobic bacteria have been isolated from endocervical cultures obtained from 644 women before vaginal or abdominal hysterectomy in our hospital during the past several years (unpublished data).[4] Fifty-eight percent of the isolates were aerobic and 42% were anaerobic bacteria. Gram-positive cocci accounted for 67% of aerobic bacteria isolated; of these, 33% were *Streptococcus faecalis* (enterococci), 33% were *Staphylococcus epidermidis*, and 16% were group B streptococci. *Escherichia coli* was the predominant gram-negative isolate and accounted for 21% of the aerobic bacteria isolated. Nine percent of gram-negative aerobic isolates were *Enterobacter* sp., *Proteus* sp., and *Klebsiella* sp. Forty-three percent of the anaerobic bacteria were gram-positive cocci and 26% were *Bacteroides bivius*. An additional 14% were members of other *Bacteroides* sp. The *Bacteroides fragilis* group accounted for 12% of preoperative anaerobes isolated. Pathogens responsible for postoperative pelvic infection are derived from these bacteria.

Incidence and type of infection

Irrespective of surgical approach, infection developing in the pelvis after hysterectomy is potentially prevented by the prophylactic administration of an antimicrobial. Neither cystitis nor pyelonephritis is prevented by prophylaxis, and elective operations should not be scheduled or performed if urinary pathogens are present. Similarly, neither microatelectasis nor pneumonia is prevented by perioperative prophylaxis, and no respiratory tract inflammation should be present when elective operation is performed. Many placebo-controlled prospective studies, as well as our own experience, have indicated that prophylactic antibiotics do not diminish the occurrence of asymptomatic temperature elevation not associated with infection. Finally, since the incidence of abdominal incision infection is so low, prophylaxis does not significantly alter its occurrence.

Although the level of infection necessary to justify perioperative antimicrobial prophylaxis for hysterectomy is a matter of considerable debate, many have indicated an incidence of 10% as a breakpoint; surgeons' goals include no postoperative infections. This may result not only in prolonged administration of perioperative antimicrobials but also in antimicrobial administration for temperature elevation after hysterectomy, whether other evidence of infection is or is not present at the time. The latter practice does not reflect failure of the regimen given for prophylaxis or elevated infection rates as much as the anxiety level of the surgeon. The practice does, however, make it difficult to accurately measure infection rates.

Risk factors

It is difficult to identify uniform risk factors for infection after hysterectomy other than those previously mentioned. Just as the incidence of infection after hysterectomy varies from hospital to hospital, so may the risk factors. While it has been reported that phase of the menstrual cycle is related to an altered incidence of infection after hysterectomy, because of the altered microbiologic features of the lower reproductive tract during different phases of the cycle,[5] the majority of studies (including our experience) indicate that there is no increased risk during either phase of the menstrual cycle.[6, 7] Further, neither preoperative endocervical bacteria nor intraoperative cardinal ligament or other surgical site bacteria that are recovered are predictive of postoperative infection.[8-11] The duration of the surgical procedure has been reported as a risk factor by some investigators[12] but has not been confirmed in more than 2000 women evaluated prospectively in our hospital. Training and experience of the surgeon also appear unrelated to risk of postoperative infection. Interestingly, results of many comparative clinical trials indicate that the pharmacokinetics and antimicrobial spectrum of an agent selected for prophylaxis, although of paramount importance in determining therapeutic efficacy for established infection, seem to have little impact on prophylactic efficacy.

Despite almost universal acceptance of the fact that women undergoing vaginal hysterectomy require antimicrobial prophylaxis, there are many private practitioners who do not routinely administer prophylactic antibiotics because of low infection rates. There are several categories of women who appear to be at higher risk for development of infection after vaginal hysterectomy. Age is a factor, with both younger[12] and older[13] women presenting an increased risk. Diabetes is also a risk factor.[13] Additional procedures such as colporrhaphy or adnexectomy may increase the risk for postoperative infection,[10, 14] as does postoperative anemia in our hospital. The postoperative course for women who undergo vaginal hysterectomy, however, is much more benign and shorter than that for women undergoing an abdominal hysterectomy.

The abdominal approach increases the risk for infection after hysterectomy.[12, 13, 15] Older age,[13, 14] obesity,[16] and diabetes[13] may be risk factors that increase infection after abdominal hysterectomy. Obesity appears to pose a problem primarily in healing of the abdominal incision, and mechanical management of the incision appears to be more important that the administration of antimicrobial prophylaxis. Excessive cau-

tery increases the incidence of nonunion of the abdominal incision.[17] Preceding procedures such as dilation and curettage or conization more than 72 hours but less than 4 weeks before hysterectomy appear to increase the risk of postoperative infection after abdominal hysterectomy[18] as well as vaginal hysterectomy.[19] Since there is significant controversy over the requirement for perioperative prophylaxis at abdominal hysterectomy,[20] individual determination is required. The use of an intraperitoneal wash has not been as well studied in the context of abdominal hysterectomy as it has been with cesarean section, but preliminary data indicate than an intraoperative wash may significantly reduce postoperative infection.

Single-dose prophylaxis

With increased experience, the duration of prophylactic antimicrobial administration has decreased from 7 days, to 5 days, to 3 days, to 1 day, to three perioperative doses by the mid-1980s. Most studies involved comparisons of multiple doses, although a few investigators reported results with single doses of various antimicrobials. Recently, attention to the costs of health care have rekindled interest in single-dose prophylaxis. A single dose of an antimicrobial for prophylaxis apparently can be effective in reducing pelvic infection after hysterectomy. The advantages of single-dose prophylaxis are numerous and obvious. In general, it is less expensive to administer one dose rather than multiple doses of an antibiotic, depending, in part, on cost of drug per gram. When less antibiotic is given, less nursing time and less pharmacy time are required. Moreover, use of space in both pharmacy and nursing units is improved. Prospective comparative studies showed that recovery of organisms resistant to an antimicrobial regimen is significantly higher after three doses than after one dose.[21, 22] Such results indicate that perhaps as few as three doses may significantly alter host flora and contribute to the development of selective resistance in bacteria. Clearly, the fewer doses administered, the less likely it is that the patient will develop either toxic or allergic adverse reactions. Having identified a need for prophylaxis and accepting the fact that a single dose is all that is required, two problems remain: which agent to administer and how to administer it.

Routes of administration

If the antibiotic is administered intramuscularly, serum and tissue levels will generally be lower but will persist longer than with intravenous administration. According to data from an animal skin model,[23] the window for efficacy of perioperative prophylaxis is approximately 3 hours in duration and is maximal if administration occurs relatively soon before operation. Although our initial impression was that patient benefits would be greater in a teaching institution if the agent were administered intramuscularly because of prolonged concentrations, more recent experience indicates that infection rates may be lower if the agent is given intravenously during 15 to 30 minutes in the operating room after the intravenous line is in place but prior to anesthesia. With the patient awake, it is possible to identify adverse reactions before the entire dose is given.

Single-dose agents

The first-generation cephalosporins cefazolin,[24] cephalothin,[25] and cephradine[26] have been evaluated as single agents in vaginal hysterectomy prophylaxis and have proved effective; however, they have not been evaluated in women undergoing abdominal hysterectomy. Single-dose cefoxitin,[21, 22] cefonicid,[27] cefotetan,[28] ceforanide,[29] cefotaxime,[30] and ceftriaxone[13] are second- and third-generation cephalosporins that have established clinical efficacy in both vaginal and abdominal hysterectomy prophylaxis. Single-dose piperacillin (unpublished data) was recently investigated in both procedures in our hospital and was found to be as effective as triple-dose cefoxitin in preventing postoperative pelvic infection.

Cefonicid, ceforanide, cefotaxime, and cefotetan are currently approved by the Food and Drug Administration for single-dose prophylaxis in hysterectomy. Prophylactic efficacy appears equivalent, although significant differences in serum and tissue half-life and cost per gram exist. Finally, we need to consider whether to administer second- and third-generation cephalosporins or newer penicillins for prophylaxis and thus possibly jeopardize their future efficacy as therapeutic agents when a first-generation cephalosporin may be as efficacious and less expensive. If efficacy is indeed equivalent, it would seem wise to continue with the first-generation agents.

Single-dose versus multiple-dose piperacillin prophylaxis in primary cesarean operation

Stanley A. Gall, M.D., and Gale B. Hill, Ph.D.
Chicago, Illinois, and Durham, North Carolina

A prospective, randomized double-blind study was undertaken to determine the safety and efficacy of single-dose versus multiple-dose piperacillin for primary cesarean operation prophylaxis. After informed consent was obtained, patients received either 4 gm of piperacillin intravenously as a single dose or three 2 gm doses of piperacillin intravenously 4 hours apart. One hundred sixteen patients were evaluated for response; postoperative infection at the operative site was prevented in 52/60 (86.6%) who received the single dose and 53/56 (94.6%) who received multiple doses. The types of postoperative infections that occurred were similar in those patients in each group who developed infection and all responded well to therapeutic drugs. No adverse reactions to piperacillin were noted. Demographic characteristics and risk factors for infection were comparable for the two groups. These data support the efficacy of single-dose prophylaxis with an appropriate antibiotic agent. (AM J OBSTET GYNECOL 1987;157:502-6.)

Key words: Single-dose/multiple-dose prophylaxis, postoperative infection

The concept of administering perioperative antibiotics as prophylaxis for cesarean operation is widely accepted.[1-3] The basic science concepts and early principles of such prophylaxis were first clearly described by Burke.[4] In the last 20 years, many investigators have studied different antibiotics, doses, and durations of therapy. In addition, factors associated with an increased risk of clinical infection have been described. Results of many studies suggest that perioperative antibiotics reduce the incidence of postoperative infection, that many antibiotics seem to offer similar benefit, that maximum doses should be used, and that the duration of therapy should be no longer than 24 hours after operation. More recent data suggest that a perioperative course of antibiotics of less than 24 hours may be equally effective,[5-7] but not all investigators agree.[8] This study was designed to compare the efficacy and safety of a single dose of piperacillin with those of a three-dose regimen in preventing postoperative infection in women undergoing primary cesarean section.

Study design

The investigation was a double-blind, randomized comparison of two prophylactic dosage regimens of piperacillin. One treatment group received a single 4 gm dose of piperacillin intravenously and the other, a total of three 2 gm doses of the antibiotic given 4 and 8 hours after the first dose.

Patients admitted to Duke University Hospital who were undergoing primary cesarean section and who were considered to be at increased risk for postoperative infection were eligible for inclusion. Increased risk was determined according to guidelines described by Gibbs.[9] The presence of any of the following constituted increased risk: labor or ruptured membranes for ≥6 hours, internal fetal monitoring >9 hours, use of an intrauterine pressure catheter, or three or more vaginal examinations.

Patients who met the entrance requirements and gave informed consent underwent a complete medical history, physical examination, and laboratory tests of a complete blood count with platelet count, blood urea nitrogen, alkaline phosphatase, serum glutamic oxaloacetic transaminase, and urinalysis. Urine cultures were obtained prior to operation if the patient's history suggested previous urinary tract infections.

On entering the study, patients were assigned to one of two treatment groups according to a computer-generated randomization schedule. Patients assigned to receive a single dose of piperacillin received 4 gm intravenously immediately after umbilical cord clamping. These patients then received intravenous infusions of normal saline solution 4 and 8 hours after the initial single dose of piperacillin. Patients in the multiple-dose group received 2 gm of piperacillin intravenously immediately after umbilical cord clamping. Additional doses of 2 gm were given intravenously at 4 and 8 hours after the initial dose. Each patient was monitored daily for adverse clinical reactions and local tolerance.

Clinical findings used to determine the presence of infection were as follows: (1) Operative site infection with a presumptive diagnosis based on (a) a temperature of ≥39° C in the first 24 hours after operation or

(b) a temperature of ≥38.5° C on two consecutive measurements at least 4 hours apart, 24 hours after delivery, and the presence of two of the following—uterine tenderness, foul-smelling cervical discharge, and no evidence that fever was associated with another cause; (2) wound infection, indicated by the presence of local induration and tenderness with purulent drainage from the incision; (3) urinary tract infection, with a urine culture containing $\geq 10^5$ organisms per milliliter; (4) lower respiratory tract infection, with radiologic evidence of pulmonary infiltrate(s) and fever.

If the patient manifested signs of postoperative infection, the following cultures were obtained: for endometritis, endometrial culture and/or culdocentesis; for wound infection, wound exudate; for urinary tract infection, urine; and for all patients evaluated for postoperative infection, blood cultures. Specimens taken for microbiologic culture were processed as previously described.[10, 11]

Results

A total of 129 patients were accessed to the study, with 64 patients in the single-dose group and 65 in the multiple-dose group. Thirteen patients, four in the single-dose group and nine in the multiple-dose group, could not be evaluated because of errors in antibiotic administration. In the single-dose group, two patients could not be evaluated because they had received other antibiotics within the previous 7 days, one was receiving concomitant antibiotics, and the fourth patient was given the prophylactic antibiotic too late. In the multiple-dose group, six of nine patients who could not be evaluated had received antibiotics within the preceding 7 days, and one each had received concomitant antibiotics, had received antibiotics too late, and had not received the first dose. The following analyses were based on the 116 remaining patients.

Table II. Indications for cesarean section

	n	%
Fetal distress	38/129	29.5
Cephalopelvic disproportion	37/129	28.7
Failure to progress	37/129	28.7
Preeclampsia	20/129	15.5
Breech	20/129	15.5
Two or more indications	87/129	67.4

Demographic characteristics and risk factors for infection are listed in Table I for the single-dose (60 patients) and multiple-dose (56 patients) antibiotic groups. There were no significant differences noted for any of these characteristics, and the two treatment groups were considered comparable. The 13 patients who could not be evaluated were demographically similar to the 116 patients who could be evaluated. The mean numbers of risk factors for infection were 2.3 ± 0.2 in the single-dose group and 2.4 ± 0.2 in the multiple-dose group.

Fetal distress, cephalopelvic disproportion, and failure to progress each accounted for about one third of the indications for operation. Most patients (87 of 129, 67.4%) had two or more indications for cesarean section (Table II).

Durations of operation were 53.9 minutes (range, 29 to 87) in the single-dose group and 55.0 minutes (range,

25 to 120) in the multiple-dose group. Patients received their first intraoperative doses at a mean of 3.7 minutes (range, −11 to 17) in the single-dose group and at an average of 3.2 minutes (range, −17 to 22) in the multiple-dose group.

Response to prophylaxis was deemed satisfactory if no infection ensued at the operative site. In the 116 patients who could be evaluated, a satisfactory response was seen in 52 of 60 (86.6%) of the single-dose group and 53 of 56 (94.6%) of the multiple-dose group (p = NS; Fisher's exact test). Operative site infections occurred in eight of 60 (13.4%) patients who received single-dose antibiotics, including seven patients with endometritis and one patient with endometritis and septicemia. Three of 56 (5.4%) patients in the multiple-dose group developed operative site infections, including two patients with endometritis and one patient with endometritis and wound infection. Culture results for the 11 patients with failure of antibiotic prophylaxis are given in Table III. Susceptibility to piperacillin was de-

termined for these isolates; only one strain of *Escherichia coli* was reported to be resistant (minimum inhibitory concentration >128 μg/ml).

Six patients judged to have satisfactory prophylactic courses developed "non–operative site" infections after leaving the hospital but within the 6-week follow-up period. These included one patient in the single-dose group who developed pelvic inflammatory disease at 6 weeks post partum and five patients in the multiple-dose group (four developed urinary tract infections and one developed an upper respiratory infection). Since these infections all occurred at least several weeks after the patient was discharged from the hospital, they were not believed to be related to operation.

Postoperative antibiotics were administered in the hospital to each patient having an unsatisfactory response to prophylaxis. In-hospital patients received primarily cefamandole, 2 gm every 6 hours, and clindamycin, 600 mg every 6 hours (seven patients), or cefamandole and metronidazole, 500 mg every 6 hours (one patient). One patient each was treated with cefamandole alone, moxalactam, 2 gm every 8 hours, and moxalactam plus clindamycin. All patients responded satisfactorily.

No adverse reactions to piperacillin were noted in either of the two treatment groups. Hematologic parameters were not affected and both dosage regimens were well tolerated.

Comment

The recent literature[2, 3] reports that patients undergoing primary cesarean section have a 10% to 85% risk of postoperative infection, depending on factors such as socioeconomic status and the presence of increased risk factors. The incidence of infection in the patient at increased risk is 40% to 85%. In contrast, the risk of morbidity in patients undergoing elective repeat cesarean operation is less than 20%. A previous study performed at the same hospital demonstrated infection rates of 40.8% in placebo-treated women undergoing primary cesarean section and 22% in those undergoing elective repeat cesarean operations when prophylactic antibiotics were not administered.[3]

In this investigation, the rate of postoperative infection in patients given a single 4 gm dose of prophylactic piperacillin was not statistically different from that observed for patients given a three-dose regimen (total, 6 gm). Similar efficacy with single-dose prophylaxis has been described previously for other antibiotics. However, because of the relatively small number of patients in each group, it is not possible to exclude a beta error. Importantly, there was no difference in the severity of the infections that developed in patients from either group, and no patient developed either septic thrombophlebitis or a pelvic abscess requiring surgical drainage. In previous studies comparing cefazolin with other antibiotics, no statistical difference was observed with respect to efficacy, although the cefazolin-treated patients seemed to be more seriously ill when they became clinically infected.

Group B streptococci were isolated from the infected endometria of two patients in the single-dose group and one patient in the multiple-dose group. In a previous study[3] with a 24-hour perioperative course of cefazolin for cesarean section prophylaxis, no group B streptococci were isolated from patients with postoperative infections. Although these observations are limited and may therefore be spurious, one wonders whether the shorter dosing schedules eliminate group B streptococci as efficiently as protocols that utilize a 24-hour postoperative course. This may be an important consideration as an increasing number of protocols dictate shorter prophylactic courses.

In this investigation, the prophylactic efficacy of a single 4 gm dose of piperacillin was not statistically different from 2 gm doses given 4 hours apart. An advantage of this study in comparing single-dose versus multiple-dose regimens was the use of the same drug in both treatment groups. This avoids the problem of confounding variables related to different spectra of activity and pharmacokinetics when two different drugs are compared for different dosing regimens.[6, 7] Results obtained with either dosing regimen of piperacillin were acceptable and comparable with those reported in other recently published studies. Some caution is appropriate, however, regarding the conclusion that single-dose and multiple-dose regimens are truly equivalent. Because of the small numbers of patients tested, the power of this trial (beta error) may be too great.

Nevertheless, if some differences in efficacy between the two regimens do exist, they apparently are not substantial. We conclude therefore that the results of this study support the use of single-dose prophylaxis with an appropriate agent for its convenience.

Cost-effective use of antibiotic prophylaxis for cesarean section

Larry C. Ford, M.D., Hunter A. Hammil, M.D., and Thomas B. Lebherz, M.D.
Los Angeles, California

Clinical experience has indicated that the prophylactic use of antibiotics reduces infectious morbidity in patients undergoing cesarean section. Several factors must be considered (for instance, in vivo and in vitro efficacy, patient allergies, side effect profiles, status of host defenses, the total cost of therapy, and the risk of selecting resistant organisms that cause superinfections) before prescribing prophylactic antibiotic drugs for this indication. Moreover, medical-legal consequences associated with potential postpartum infections must be considered in assessing the costs and impact of a prophylactic regimen. Results of comparative antibiotic trials in indigent patients undergoing cesarean section demonstrated differing rates of successful antibiotic prophylaxis: piperacillin, 98%; cefoxitin, 91%; cephalothin and ceftazidime, 82%; cefotaxime, 80%; and ampicillin, 77%. Although the acquisition costs of antibiotics vary greatly, these costs are dwarfed by the substantial cost savings that can be realized by use of broad-spectrum antibiotics, which, in our hands, have resulted in reduced laboratory and pharmacy expenses and decreased hospital stays for both mother and neonate. Controlled studies designed to investigate microbiologic as well as clinical efficacy of antibiotics are indicated. Further refinements in individualizing antibiotic regimens according to patient population should be sought. (AM J OBSTET GYNECOL 1987;157:506-10.)

Key words: Cesarean section, prophylaxis, chemiluminescence, chemotaxis

Antibiotic prophylaxis of infection for women undergoing cesarean section differs from that used in gynecologic operations and other surgical procedures because of the presence of the fetus. In contradistinction to other surgical procedures, in which it is desirable to have effective antimicrobial levels present in the tissues at the time of operation,[1] antibiotics are usually withheld from women undergoing cesarean section until after the cord is clamped. Despite this difference in timing of antibiotic administration, however, clinical experience has shown that the incidence of postpartum infection can be decreased by the use of antibiotics.[2-8]

Antimicrobial selection

Identifying pathogens. Several factors should be evaluated when one is selecting an antimicrobial regimen for cesarean section prophylaxis. For example, the presence of potentially pathogenic microorganisms, including the *Bacteroides* group, anaerobic cocci, the pyogenic cocci (including enterococci), and facultative gram-negative rods—which can be part of the vaginal and cervical flora in asymptomatic women[9-11]—complicates the interpretation of culture results from patients who develop fever after receiving antibiotic prophylaxis (Table I). The difficulties involved in obtaining meaningful uterine culture material from patients with the clinical diagnosis of endomyometritis have been discussed by several investigators.[12-15]

We previously reported the use of "double-lumen tubes" to decrease contamination from the cervix and vagina.[13] However, because these devices are more complex than regular swabs, inconsistent use during nocturnal fever evaluations has limited their value on our

service. Therefore we have not been able to collect contamination-free culture data on all of our patients with a diagnosis of endomyometritis after cesarean section. Nevertheless, use of the double-lumen tubes has shown that our data are in excellent agreement with those reported by other investigators.[12-17] The most common bacterial species isolated from the infected uterus after cesarean section in our patients as in others are *Peptococcus, Bacteroides, Peptostreptococcus, Escherichia coli,* and enterococci, followed by other species of pyogenic cocci and facultative gram-negative bacilli (Table I). Such information regarding antibiotic failures should be useful in determining what an effective prophylactic antibiotic spectrum should include or protect against.

Status of host defenses

The physician must also consider the status of the patient's host defense mechanisms in choosing an antibiotic for prophylaxis. For example, the antimicrobial activity of amniotic fluid in our obstetric patients, who are primarily indigent, is generally poor and thus probably contributes to their relatively high rates of postpartum infections[18, 19] (Table II).

In contrast, most "private patients" at the same institution have excellent antimicrobial activity in the amniotic fluid and very low postpartum infection rates,[18, 19] which illustrates the importance of individualizing antibiotic use and selection (Table II).

The importance of interactions between antibiotics and host defenses has recently been recognized. For example, we and other investigators previously reported on the effects of antibiotics on many polymorphonuclear leukocyte functions, including chemiluminescence and chemotaxis, both of which are enhanced by piperacillin and clindamycin and depressed

Table II. Noncellular host defenses for amniotic fluid

by some of the cephalosporins. Cefotaxime, for example, depresses these essential polymorphonuclear leukocyte functions[20-25] (Table III). Whether and how these in vitro data will correlate with significant clinical findings are still being studied. Nevertheless, the effect of an antimicrobial on polymorphonuclear leukocyte functions, particularly in indigent populations, may emerge as an important consideration in choosing a prophylactic antibiotic.

Discouraging bacterial resistance

The effects of antibiotic use on the emergence of resistant organisms should be thoroughly thought out. The use or misuse of antibiotics affects not only the individual patient but also both hospital and community environments.[26-31] Despite rigorous policies of infection control, house staff and nursing staff interact with and cross contaminate gynecologic oncology patients, benign disease gynecologic patients, and obstetric patients, thus enlarging the pool of potentially resistant microorganisms. Use of antibiotics that are strong inducers of β-lactamases should be carefully considered in view of their potential for increasing bacterial resistance to a variety of antimicrobials.[30] Adverse changes in microbial sensitivities and pathogenicities can occur as a result of prescribing practices. For example, the emergence of enterococci as postoperative pathogens certainly has been attributed to antibiotic use.[32, 33] More important, given the potential for cross contamination and the spread of resistant anaerobes (for example, *Bacteroides*) and gram-negative facultative bacilli (for example, *Pseudomonas, Proteus, Serratia*), physicians need to be increasingly aware and vigilant to help control these problems.

Clinical trials (University of California at Los Angeles experience)

Over the past several years, we prospectively evaluated the prophylactic efficacy of several β-lactam antibiotics including ampicillin, cefoxitin, cefazolin, ceftazidime, cefotaxime, and piperacillin in our indigent patients undergoing cesarean section under similar conditions.[5-7] All patients received 2 gm each of the

*Random migration was 37 ± 4 μm.

Table IV. Cost of failure of antibiotic prophylaxis in cesarean section patients

Maternal (isolation bed)	$447 × 5 days = $2235
Newborn observation bed	$614 × 5 days = $3070
Fever workup (mean)	$ 570
Clindamycin, gentamicin	$1251
Intravenous sets, pharmacy charges laboratory fees (creatinine, blood urea nitrogen, peak and trough)	$158 × 2 days = $ 316
Total	$7442

Table V. Cesarean section prophylactic study at the University of California at Los Angeles: Cost of antibiotic failure and subsequent therapy of infection per 100 patients

Piperacillin	$ 27,744
Cefoxitin	$ 81,078
Cefazolin	$139,056
Cefotaxime	$169,540
Ampicillin	$181,966

Table VI. Cost savings associated with piperacillin compared with other prophylactic antibiotic regimens in cesarean section

Piperacillin versus ampicillin	$154,222
Piperacillin versus cefotaxime	$141,796
Piperacillin versus cefazolin	$111,312
Piperacillin versus cefotaxime	$ 53,334

study drug when the umbilical cord was clamped and two additional doses of 2 gm each at 4-hour intervals.

Exclusion and efficacy criteria. Patients were excluded from the study if they had had any of the following: antimicrobial therapy within 7 days before entry into the study, a history of hypersensitivity to either penicillins or cephalosporins, renal and/or hepatic function tests substantially outside normal limits, or evidence of infection at the time of enrollment into the study.

Both direct and indirect criteria for the existence of postoperative morbidity were used to evaluate the efficacy of the antibiotic regimens: fever, duration of hospitalization, administration of systemic antibiotics after operation, and evaluation of wound healing and evidence of infection at the operative site. Febrile morbidity, as a manifestation of infection, was defined as an oral temperature ≥100.4° F on at least two occasions 4 to 6 hours apart, occurring more than 24 hours after operation. A satisfactory prophylactic response was defined as no bacterial or clinical infection at the operative site for 4 to 6 weeks after operation. An unsatisfactory prophylactic response was defined as the development of an infection at the operative site that required antibiotic administration during the initial 4- to 6-week postpartum period. Patient demographics and other variables such as the mean number of vaginal examinations, the mean time of ruptured membranes, the mean blood loss, the mean duration of operation, and the mean experience of the surgical team did not vary significantly among study groups.

Results

With the above criteria, the response to prophylaxis was considered effective in 98% of piperacillin-treated, 91% of cefoxitin-treated, 82% of ceftazidime-treated, 82% of cefazolin-treated, 80% of cefotaxime-treated, and 77% of ampicillin-treated patients. Statistically, there was a significant difference ($p = 0.035$) between the piperacillin and cefoxitin efficacy rates. Interestingly, however, there were no significant ($p < 0.05$) differences between the third-generation and first-generation cephalosporins.

To determine the extent to which the clinical success of prophylaxis could be translated into patient cost savings, the total mean costs of prophylactic failure in cesarean section were calculated. These patient costs were based on the minimum mean charges of treating in-

fections after cesarean section, including daily charges for hospital rooms (both maternal and normal nursery), laboratory tests and fees, and costs of drugs, pharmacy preparation, and intravenous equipment as of July 1, 1986 (Table IV). Significant but more difficult to determine than the above fees are the costs of potential medical-legal complications arising from patient anger and anguish associated with morbidity, as well as additional physician and nursing time to evaluate and treat the antibiotic failures. Given these data and our current costs, the estimates per 100 patients for failure of each drug are: ampicillin, $181,966; cefoxitin, $81,087; cefazolin, $139,056; cefotaxime, $169,540; and piperacillin, $27,744 (Table V).

Conversely, when the cost of 100 prophylactic failures for the most effective agent, piperacillin, was compared with the costs of ampicillin, cefotaxime, cephalothin, and cefoxitin, savings were $154,222 (piperacillin versus ampicillin), $141,796 (piperacillin versus cefotaxime), $111,312 (piperacillin versus cefazolin), and $54,334 (piperacillin versus cefoxitin), respectively (Table VI).

Pragmatically, the only correct prophylactic antibiotic regimen is whatever works best in the physician's own experience. However, if one's current prophylactic antibiotic regimen has a failure rate of 5% or higher, we recommend that consideration be given to an antibiotic with a broader spectrum of coverage, particularly of the enterococci and anaerobes.

Comment

In conclusion, the practicing obstetrician and gynecologist, before prescribing an antibiotic, must carefully consider, in addition to antimicrobial spectrum, the patient's allergies, the drug's potential toxicities, and the medical-legal implications of any prophylactic antibiotic failures. We must remember that drug costs include both acquisition costs and the costs for treating infections related to prophylactic failures. Diagnosis-related groups (DRGs), government regulations, and third-party payers have forced physicians to become more aware of financial considerations and to take a more active role in cost control. We are increasingly torn in several, often conflicting directions. On the one hand, we need to recognize the importance of and take part in containing and minimizing the costs of health care. On the other hand, we must never relinquish our responsibility to base medical decisions on the best interest of our patients. To ignore the cost containment issues involved in either the current DRGs situation or the malpractice crisis is to ignore reality. Nevertheless, physicians should not relinquish the control of therapy and the management of patients because of nonmedical, economic pressures.

Physicians should utilize antibiotic regimens that are both clinically effective and cost effective. Whenever possible, single-agent therapy rather than combination therapy should be used if clinical efficacy and safety can be demonstrated.

We wish to thank Dr. Elliot Landau of the Department of Biomathematics, University of California at Los Angeles, for his assistance in the statistical analysis of our data.

Questions from the audience

The following highlights are excerpted from two informative and spirited question-and-answer sessions, moderated by F. Gary Cunningham, M.D., Symposium Chairman.

Session 1

Q. Dr. Gall, could you reiterate the failure rates of the two prophylaxis regimens you used in your study—the triple-dose course of piperacillin versus the single dose?

Dr. Gall. The multi-dose regimen was successful in approximately 94% of patients compared with 87% for the single-dose group. Although these figures were not significantly different, I originally expected that they would be. That's the nice thing about a randomized, blinded, prospective trial: your own bias is irrelevant.

Moderator. Dr. Gall, what kind of infection rate could you have expected in your population if no perioperative prophylaxis had been administered?

Dr. Gall. On the basis of previous placebo studies, we might have expected a postoperative incidence of infection in the range of 45% to 50%.

Moderator. This is an important point because our background infection rate in high-risk patients at Parkland Hospital in Dallas is probably closer to 85% without perioperative prophylaxis. We should remember that most of these investigations are carried out in high-risk women from low socioeconomic groups in large urban hospitals. It is likely that single-dose prophylaxis would be much more effective for most of the private patients treated by the practitioners in our audience than for our patients in Chicago or Dallas.

Dr. Gall. In 1979, we published results of a study conducted at Duke University in which cefazolin was compared with placebo for patients undergoing cesarean section. Socioeconomic status, defined as public patient versus private patient, was one of the factors we looked at. We found a difference: the worst case scenario was placebo in a public patient, which resulted in a 51% infection rate. The same placebo in private patients resulted in a 40% incidence of infection. We don't really know whether these differences can be attributed to better protoplasm, or fewer bacteria, or other factors, but it may indeed be true that the shortest course of a prophylactic antimicrobial—the single dose—may be quite adequate for most private patients.

Q. Dr. Gall, could you comment on the significance, if any, of isolating mycoplasmas in so many of your patients who became infected?

Dr. Gall. Among infected patients, there was a much higher, albeit statistically nonsignificant, incidence of mycoplasmal colonization. Other investigators also have alluded to the possibility that the presence of mycoplasmas in the amniotic fluid might be a kind of marker for the development of clinical postoperative endometritis.

Moderator. Dr. Gall, did you isolate any enterococci in your postoperative cultures?

Dr. Gall. Yes, there were a few enterococci, but I only worry about them if they are isolated from the blood or from an immunocompromised patient.

Moderator. I agree with you, but I am worried about what happens with enterococci in 10 years. For instance, the "sin" of antimicrobial misuse is catching up with us in that we are now seeing methicillin-resistant *Staphylococcus aureus* catheter-associated infection in intensive care units. We are paying dearly for such past practices by treating patients with expensive intravenous vancomycin. It would behoove all of us to keep abreast of the literature and clinical evaluations of various drug regimens lest we risk using therapies that are becoming ineffective.

Session 2

Q. How do the third-generation cephalosporins penetrate into difficult-to-reach areas, or across biologic membranes, compared with penicillins?

Moderator. First of all, we've got to understand that a drug may be present in an abscess, for instance, without exerting any biologic activity. These things are actually becoming more difficult to study because more prophylaxis and more vigorous treatment with better drugs are making pelvic abscesses much less common than they used to be. Most of our data on abscess penetration therefore come from the rat model of Gorbach et al.

Q. I just find it surprising that a large cephalosporin-type molecule would be able to penetrate at all.

Dr. Hemsell. Penetration probably does not occur in undamaged meninges, for example. Inflamed meninges, on the other hand, apparently react differently.

Dr. Gall. The concentration of bacteria and the concentration of enzymes that break down inactive metabolites are several logs higher in an abscess. Even if an antibiotic gets in, it is in a much more hostile environment. The pH is lower and the polymorphonuclear leukocytes are probably not functioning well.

Moderator. In the final analysis, we have to look at whether these experimental results correspond in any way with clinical outcomes. Although we who are interested in research have to continue to get answers to questions about penetration, half-lives, serum levels, etc., the bottom line has to be, "does the drug work?" and "how long will it continue to be effective?"

Q. How should chorioamnionitis be managed?

Moderator. I think we can all agree that a woman with chorioamnionitis needs to be delivered. If she's not in labor already, labor should be induced. Moreover, we should treat these patients vigorously with some sort of intensive antimicrobial regimen during labor.

I am troubled, however, by those individuals who are recommending that delivery by the most expeditious route—cesarean section—be undertaken when chorioamnionitis is diagnosed. On the basis of my clinical experience, it seems that cesarean section in a laboring woman who has ruptured, leaking membranes, fever, and clinical chorioamnionitis can result in some pretty severe outcomes. The babies do not seem harmed by at least a trial of labor if appropriately monitored, and the mothers do better with vaginal deliveries.

Dr. Gall. At our institution, patients diagnosed as having chorioamnionitis and who have a temperature of ≥38° C are started on an antibiotic every 6 hours. We obtain a culture and induce labor or allow labor to proceed for 4 to 6 hours. If appropriate progress has not been made after a reasonable trial, the patient would probably be delivered of her infant by cesarean section. The antibiotic is continued for 72 hours post partum or for 24 hours after the patient becomes afebrile.

Moderator. I'd like to emphasize the fact that patients with chorioamnionitis who are delivered of their infants by cesarean section need intensive therapy with something. A few years ago, we used penicillin plus an aminoglycoside with poor results: a third of those women ultimately required hysterectomy within the first 10 days post partum for parimetrial phlegmons, broad ligament abscesses, and things of that nature. It's best to use the kind of "big gun" regimen—such as clindamycin and gentamicin, a cephalosporin with chloramphenicol, or piperacillin alone—that would be appropriate for the worst kind of pelvic sepsis. When a surgical delivery has been performed, chorioamnionitis presents a serious threat to maternal health.

In summary, we know that women with significant pelvic infections suffer some sort of breach of the epithelial defenses, either from surgical trauma or from infection with a primary invading organism (for example, *Neisseria gonorrhoeae, Chlamydia trachomatis*). We also know that these infections are polymicrobial.

The overuse of certain drugs, such as cephalosporins, has resulted in the emergence of bacterial strains that are resistant to some currently used regimens. Dr. Galask described a particularly interesting and important mechanism of gram-negative resistance—induction of β-lactamase production by exposure to certain β-lactam agents. It sounds theoretical, but we're already dealing with the clinical implications of this phenomenon in terms of increased resistance to cefoxitin.

In his discussion of therapy for serious female pelvic infections, Dr. Hemsell emphasized that the standard for any regimen—whether it is clindamycin plus gentamicin, or piperacillin—is a 90% to 95% success rate. I prefer to use single-agent therapy whenever efficacy is equivalent.

Enhancement or depression of polymorphonuclear leukocyte functions by antimicrobial agents, addressed by Dr. Ford, is a fascinating aspect of infection control. Moreover, he showed us how the higher overall costs of less effective prophylactic regimens underscore the importance and impact of using appropriate, effective surgical prophylaxis, particularly in high-risk patients.

While it still may be a theoretical problem, I am nevertheless disturbed by the finding that many women who receive perioperative prophylaxis have enterococci in the lower genital tract for 2 to 5 days after operation. It makes me think that piperacillin, which is quite effective against enterococci, will become more and more attractive as a prophylactic agent in the future.

In general, piperacillin is an ideal single agent for prevention and therapy of female pelvic infection. It has an excellent antibacterial spectrum, is clinically effective, and enjoys the safety of the penicillins. Its future value is not jeopardized by β-lactamase induction but rather is enhanced by its somewhat unique activity against enterococci. Finally, its cost is reasonable and competitive. I'd like to thank the faculty for their outstanding presentations and the audience for providing such stimulating discussion.

CORRESPONDENCE

Profound hypotension complicating magnesium therapy

To the Editors:

I agree with Bourgeois et al. (AM J OBSTET GYNECOL 1986;154:919-20) that significant hypotension with nontoxic magnesium levels is not a generally recognized side effect of magnesium sulfate therapy in preeclamptic patients. However, I disagree with the authors regarding their statement that there is no support for the possibility that severe hypotension can be caused by the concomitant administration of magnesium and promethazine.

Promethazine, a phenothiazine derivative, is a selective calmodulin inhibitor.[1] This pharmacologic action of the drug can promote vascular smooth muscle relaxation, vasodilatation, and hypotension by the following two mechanisms: (1) an indirect, β_2-sympathomimetic type of vasodilatation, caused by the calmodulin-mediated inhibition of phosphodiesterase,[1] and (2) a direct inhibition of vascular smooth muscle contractility by selective inhibition of calmodulin, the actin and myosin filament–coupling molecule.[2]

The concomitant administration of a calcium antagonist (magnesium sulfate) and a phosphodiesterase and calmodulin inhibitor substance (promethazine) can be responsible for the severe hypotension observed in the two patients described by the authors, despite their extensive clinical experience.

One should be aware of drug interactions, especially with magnesium sulfate in conjunction with β-sympathomimetic, vasodilator, calcium antagonist, and phenothiazine drugs.

At the Baragwanath Maternity Hospital, where 32,000 patients are delivered of infants annually and the incidence of hypertension in labor is 4.9%, we use hydroxyzine hydrochloride (Atarax), a nonphenothiazine antihistamine with meperidine, for all our patients on a regimen of magnesium sulfate therapy. We never recorded any significant episode of hypotension.

In conclusion, Bourgeois et al. alerted us to the dangerous interaction between magnesium and a phenothiazine derivative. In preeclamptic patients receiving magnesium sulfate therapy and parenteral analgesia, a non-phenothiazine antihistamine such as hydroxyzine hydrochloride should be used.

Fetal heart rate monitoring

To the Editors:

In their article last November (AM J OBSTET GYNECOL 1985;153:685-92), Fukushima et al. considered the limitations of autocorrelation in fetal heart rate monitoring. For antenatal fetal heart rate monitoring they recommended that the fetal electrocardiogram be recorded from the maternal abdomen. Their article ignored three important points.

First, at 27 to 33 weeks of gestation it is difficult, and often impossible, to detect the fetal electrocardiogram. This is the age at which critical decisions must be made whether to deliver prematurely by cesarean section those infants whose conditions are compromised as a result of preeclampsia or placental insufficiency.

Second, the new generation of ultrasound detectors, with autocorrelation and improved transducer design has made it possible to obtain reliable fetal heart rate traces over these critical weeks. The older peak detectors had an unacceptably high signal loss, now reduced to 4% at 28 weeks.[1] Signal loss can occur as a result of maladjustment or through fetal movement, hiccups, or arrhythmia, but it can be detected at once with a microprocessor on line to give a visible or audible signal. We have used the newer ultrasound fetal heart rate monitors for the past 4 years (about 5000 records a year) and have not failed to obtain a satisfactory antenatal record.

Third, the suggestion that each pulse interval must be measured for clinical purposes is incorrect. Fetal heart rate variation can be measured from the pulse intervals averaged over 3.75 seconds as the mean minute range (in milliseconds).[1] This provides a wide discrimination between normal mean values at 32 weeks (44 msec), the lower limit of normality (less than a third percentile, 31 msec), and the reduced variation symptomatic of hypoxemia (21 msec) before development of acidemia.

Reply

To the Editors:

We thank Drs. Dawes and Redman for their comments on our article. The major cause of our differences seems to arise from a misunderstanding of the terms fetal electrocardiography and fetal heart rate variability. The ensuing discussion will clarify this situation.

A discussion of fetal electrocardiography is not meaningful unless the data acquisition system is defined. From the letter by Dawes and Redman we gather that they are using a single bipolar electrode system for external fetal electrocardiography (HP8040A). If so, we agree that the fetal electrocardiogram may not be recoverable during certain periods of gestation. The data acquisition system mentioned in our report is not a single bipolar electrode system, but as stated it is a multiple amplifier parallel group averaging system—in this case a 20-bipolar electrode system.[1] Because the study of fetal electrocardiogram with the use of this technique is in its early stages, we are not advocating its use but rather suggesting that this approach seems to be more reasonable than the mathematical and statistical manipulation of an imprecise biomechanical signal. The capabilities of this system are illustrated by Figs. 7 and 8 in the article, which were recorded during late labor.

Dawes and Redman view the new generation of ultrasound detectors that use autocorrelation as a definite improvement over the older, Doppler ultrasound–based systems and cite their experience in over 20,000 cases in which they were able to infallibly obtain satisfactory tracings. We do agree that the autocorrelated ultrasound signal produces fetal monitoring records of more pleasing appearance more often than the uncorrelated ultrasonic signal. However, the use of autocorrelation in fetal monitoring is a double-edged sword. If on the one hand we have a higher signal recovery rate and an improved tracing, we are never completely sure as to the origin of the signal unless the fetal electrocardiogram is recorded simultaneously or the fetal monitor is continuously monitored by trained personnel. Because the autocorrelation circuitry will reinforce any periodic noise originating from the fetus (e.g., fetal motion, hiccups), the mother (e.g., vessels, viscera), or the transducer-skin interface, a dangerous situation may result that may not be obvious to the clinician because of the cosmetically improved appearance of the fetal heart rate.[2,3]

It is clear from the letter by Dawes and Redman that the variability they are discussing is not the same as that based on the fetal electrocardiogram R-R intervals. Because we have no experience with extensive processing of relatively imprecise ultrasonic signals of this nature, we are in no position to discuss their findings. However, if the R-R intervals of high quality fetal electrocardiogram signals are adequately processed, there is little doubt that individual intervals are clinically important. If they are averaged for even a few seconds, it would not be possible to identify severe fetal heart arrhythmias such as premature ventricular contractions, sinus pause, or evanescent cardiac arrest. Additionally, because the degree of variability obtained with Doppler ultrasound differs with the degree of signal processing, the resultant electronic fetal monitor record reflects both physiologic data and instrumental manipulation. Unfortunately, at any given moment it is not possible to determine which component is the dominant factor. Hence, a clear distinction has to be made between fetal heart rate variability and electronic fetal monitor variability. The electronic fetal monitor is but a clinical tool; to fully use its capabilities, one must also be aware of its limitations.

Recurrent spontaneous abortion and human leukocyte antigen DRw8

To the Editors:

Through the years many authors have reported that human leukocyte antigens play an important role in the immunologic interaction between mother and fetus. We have studied human leukocyte antigen frequencies and sharing of human leukocyte antigens in 30 Japanese couples with early recurrent spontaneous abortion of unknown cause and 72 Japanese healthy couples with more than three children.

Table I shows the most interesting results of immunogenetic studies. Apparently, the female subject in patient groups has a significantly lower frequency of DRw8 antigen (0%), as compared with the controls (30.6%) ($x = -11.6$, $p < 0.0001$, corrected to $p < 0.003$). Furthermore, other previously published literature[1,2] showed few numbers of DRw8-positive women with recurrent spontaneous abortion.

Caucasian populations have a low gene frequency (2% to 3%) of DRw8 antigen as compared with the Japanese (15%). Thus it was unclear that with recurrent spontaneous abortion the number of DRw8-positive women was statistically low as compared with normal couples. The fact that there are few DRw8-positive women with recurrent spontaneous abortion seems to be meaningful.

Table I. Frequencies of DR human leukocyte antigens in Japanese control groups and patients who experienced recurrent spontaneous abortion

*Female patient versus control female $p < 0.00015$, corrected to $p < 0.003$.

Conversely, in renal transplantation, Hendricks et al.[3] reported that the DRw6-positive recipients experienced rejection of their grafts much more rapidly than the DRw6-negative ones. Kashiwagi[4] reported that only DRw8-positive recipients had nearly 100% of 3-year survival despite human leukocyte antigen compatibilities.

In pregnancy and in renal transplantation, there may exist a low or high responder to isoantigens. The possibility exists that the DRw8-positive woman is more likely to induce maternal-fetal tolerance than the others. This new finding needs to be confirmed in future studies.

Sharing of human leukocyte antigens (A, B, C, DR, and DQ) between the couples is more common among patient groups than the normal ones. This result supports the findings of other authors.[5] Although this meaning remains obscure, it may be related to the production of blocking antibody.

Myocardial infarction in the puerperium

To the Editors:

In the article entitled "Acute myocardial infarction in the puerperium in patients receiving bromocriptine" (Am J Obstet Gynecol 1986;155:371-2) Iffy et al. reported on two cases of acute myocardial infarction in the puerperium and implicated bromocriptine as the causative agent. In my opinion the authors have not presented sufficient evidence to justify this conclusion.

Myocardial infarction is a rare but previously reported complication of the puerperium in patients who have not received bromocriptine.[1] Because coronary vasospasm and myocardial infarction are well established side effects of treatment with ergonovine,[2] the administration of this medication to one of the reported patients seems sufficient cause to explain the event. The authors theorize that bromocriptine may have been

contributory via an "inborn error of metabolism," which may have resulted in an inability of the patient to distinguish between hydrogenated and nonhydrogenated ergot alkaloids or an interaction between ergonovine and bromocriptine at the P_{450} microsomal enzyme system that may have led to potentiation of the action of ergonovine. Because the established pharmacologic action of bromocriptine is to cause vasodilatation and hypotension,[3] I find the authors' alternative explanation of its pharmacologic action interesting but totally speculative and without scientific support.

The second patient reported by Iffy et al. had an autopsy that revealed an occlusion of the anterior descending branch of the left coronary artery by thrombotic emboli, which resulted in the subsequent infarction. Because bromocriptine has no known effect on coagulation and thrombus formation, it is highly unlikely that the medication contributed to the clot formation in this patient. Other thrombotic complications of pregnancy are also seen and are thought to be caused by known hypercoagulable changes in the clotting mechanism that occur around the time of delivery.[4] This hypercoagulable condition may have contributed to the coronary artery thrombus formation in the aforementioned patient and in other cases of postpartum myocardial infarction previously reported.

Thank you for your consideration of these comments.

Reply

To the Editors:

While focusing on the "proven pharmacologic action" of bromocriptine, Dr. Harold Feldman seems to overlook the fact that our article referred to the drug's untoward effects and not the predictable ones. Of the former, the product information by Sandoz Pharmaceuticals Corp.[1] quotes several dozens, including "signs and symptoms of ergotism." Because bromocriptine is an ergot derivative, this side effect should not be surprising. Accordingly, we do not think that our proposed interpretation of the pathologic mechanism of this phenomenon is "without scientific support."

We have searched the literature in vain for investigations concerning the combined effects of ergonovine and bromocriptine in the puerperium. If, as we suspect, the writer shares our ignorance in this regard, he cannot be satisfied more than we are about the absence of a potential relationship, whether simply additive or synergistic, since these two drugs are often used together post partum. It appears that we are not the only ones who are not reassured that the existence of a connection between the actions of Ergotrate and bromocriptine is "totally speculative." Since 1985, the manufacturers have found it fit to warn physicians that Parlodel rarely "may cause hypertension" and that "particular attention should be paid to patients . . . who have received within the preceding twenty-four hours other ergot alkaloids . . .."

With regard to the causation of coronary thrombosis, Dr. Feldman elects to emphasize hypercoagulability and disregards vasospasm. Our article made it clear that it was the latter effect that we considered potentially attributable to bromocriptine and not the former one. In support of this interpretation, our article referred to reported observations pertaining to the occurrence of episodes of vasospasm among patients taking bromocriptine.

We concur with Dr. Feldman that our article offered no sufficient evidence to prove a cause-effect relationship between the postpartum use of bromocriptine and the occurrence of myocardial infarction or other accidents deriving from vasospasm.[1] However, it appears to us that with regard to the routine prescription of Parlodel to healthy mothers for the purpose of ablactation, it is the safety of the drug that needs to be established beyond reasonable doubt and not its dangers.

Venous thrombosis in patients with cardiac pacemakers and oral contraceptive use

To the Editors:

I have been interested in thrombosis and pulmonary embolism for the last 20 years. Also I have implanted about 2000 cases of permanent cardiac pacemakers, in both young and old, for the last two decades. I feel the conclusion drawn by Halub et al. (Thrombosis due to

permanent pacemaker and oral contraceptives. Halub MF, Robbie G, Deere LF. AM J OBSTET GYNECOL 1985;153:571-2) is not supported by the data. I have seen vascular thrombosis of the upper torso in patients who had pacemakers implanted and who were not using oral contraceptives. I have also seen the same problems in men and women without pacemakers. The overall incidence of venous thrombosis in cardiac pacemaker patients is less than 2%.[1] In fact, I have seen this phenomenon in only two patients in the last 500 implants; neither patient was using oral contraceptives.

I do agree with the authors' discussion and management of the case. It may be that the oral contraceptives aggravated the thrombosis and the authors preferred to take an alternate approach to contraception. However, there are not enough numbers to support the authors' conclusion that "oral contraceptive therapy is contraindicated in women with permanent venous pacemakers."

Femininity—a problem(?)

To the Editors:

As a qualified gynecologist, I was asked to review the records of a local abortion center, to confirm that all local rules and regulations in Cleveland's abortion laws were not abridged and were properly observed. These were never broken, but I was deeply disturbed by the frequency of repeat abortions in some patients. In this group, repeat procedures were often done at 3- to 4-month intervals. Review of the counseling techniques and procedures showed they were proper but of no help in this group. The repeat pregnancies were not accidental.

While attempting to investigate the causes of the early repeat pregnancies, I was given a book stating that pregnancy was a major method that confirmed to the patient that she possessed full femininity. However, because of varying social or economic reasons, the pregnancy was not carried to term. I tried to get additional data from the author but failed to get any response. Shortly thereafter, I restudied a scientific exhibit on premenstrual tension that I had presented to The American College of Obstetricians and Gynecologists in 1956. At that time, I reported that three of four patients had symptoms of the disorder but only one in 10 complained. In an attempt to answer this problem, I called a meeting of the entire group of patients. The most frequent answer was, "Doctor, I am a woman and this is the price we all pay for being women!" Therefore we have two aspects of femininity. One accepts the symptoms of the premenstrual syndrome but continues to work. The other gets pregnant and then aborts. If the patient can accept either phase, this condition is acceptable, but if she does not, this then becomes a real problem.

Thus we have two groups of women, almost two generations apart, in degree, accepting the same concern. Recently, I discussed this problem briefly with Dr. Luella Klein, the recent Past President of The American College of Obstetricians and Gynecologists who is actively fighting the occurrence of unwanted pregnancies. She told me that this is one of the greatest problems encountered and that many groups are working very hard in attempts to take these and similar thoughts away from women. Should she and her associates be successful, we may have the answer on how to more fully prevent the truly unwanted pregnancy.

I pray and hope that all physicians will understand the problem I have presented and will do their very best to overcome it, assuring women that unwanted pregnancies are not a desirable answer to femininity.

Definitions of sensitivity, specificity, false negative results, and false positive results

To the Editors:

The article by Kogon et al. (Kogon DP, Oulton M, Gray JH, et al. Amniotic fluid phosphatidylglycerol and phosphatidylcholine phosphorus as predictors of fetal lung maturity. AM J OBSTET GYNECOL 1986;154: 226-30) suggests that phosphatidylglycerol and phosphatidylcholine phosphorus are reliable indicators of fetal lung maturity. However, they have incorrectly defined sensitivity, specificity, false positive rate, and false negative rate. Sensitivity is defined as the percent of individuals with a disorder in which a test predicts for this disorder. In this case, the disorder is fetal lung immaturity and the test is the determination of phosphatidylglycerol. The absence of phosphatidylglycerol is the predictor of disease. Therefore the sensitivity should be 78.3%. The improper definition of sensitivity led the authors to incorrectly state their specificity as 78.3%. Specificity is defined as the percent of individuals free of disease with a negative test (that is, the presence of phosphatidylglycerol). Therefore 592 out of 620 patients had a negative test, for a specificity of 95.5%.

In addition, the authors have confused the false positive rate with the probability of a false positive result. The false positive rate is the percent of false positives out of the *total* number of *positive* results. In this study, there were 28 false positive results out of 64 positive results or 43.7%. The false negative rate is defined as the percent of false negative results out of the total number of negative results; 1.7% in this study.

Proper use of the definitions of sensitivity and specificity will also lead to a reversal in the positive predictive value and the negative predictive value; the positive predicted value should be 56.3% and the negative predicted value should be 98.3%.

Although the conclusions, with the exception of the false negative rate and the false positive rate, remain basically intact, strict adherence to the definitions of sensitivity and specificity will eliminate errors in the construction of a binomial table and facilitate comparison among investigators.

Haemophilus influenzae infection and midtrimester abortion

To the Editors:

It is always dangerous to state that "this is the first case" or "this is the only case" when reporting an unusual event. Certainly we have all missed one or even a series of examples of the same phenomenon. An example of such a situation pertains to the report by Winn and Egley concerning *Haemophilus influenzae* chorioamnionitis (Winn HN, Egley CC. Acute *Haemophilus influenzae* chorioamnionitis associated with intact amniotic membranes. AM J OBSTET GYNECOL 1987;156:458). We reported a nearly identical case in 1979,[1] which demonstrated a systemic infection followed by intrauterine infection and delivery in the second trimester.

WANTED: Obstetrician/Gynecologist, Board Certified or eligible physician to join existing 3 member OB/GYN Department in 22 member multi-specialty group practice in the Lakes Region of central N.H. Position offers an outstanding professional, financial, and life-style opportunity. Respond with C.V. to Alan Awrich, M.D., Laconia Clinic, 724 Main Street, Laconia, NH 03246.

REPRODUCTIVE ENDOCRINOLOGY FELLOWSHIP
Louisiana State University School of Medicine in New Orleans

The Department of Obstetrics and Gynecology offers an accredited fellowship in Reproductive Endocrinology beginning July 1988. The fellowship is a two year clinical and research oriented program. Applicants must have completed an approved residency in Obstetrics and Gynecology by June 1988. The clinical services are located at the Charity Hospital and Southern Baptist Hospital in New Orleans. Research opportunities include ongoing programs in andrology, and fertility and sterility problems including an IVF/ET service as well as basic research involving the rodent, primate and pig models. Both clinical and laboratory research are encouraged and supported by local, regional, national and international agencies. Applications, including curriculum vitae, bibliography, and the names and addresses of at least three references should be sent before December 1987 to:

Krishna B. Singh, M.D.
Associate Professor and Chief
Section of Reproductive Endocrinology

Obstetrician Gynecologist

THE MICHAEL REESE HEALTH PLAN, a well-established and rapidly-expanding, federally-qualified HMO seeks Board Certified/Eligible Obstetrician/Gynecologists.

THIS POSITION entails both outpatient and hospital practice as well as medical students and house staff teaching.

REMUNERATION is high and competitive with academic and fee-for-service practice markets. Fringe benefits are generous.

INTERESTED APPLICANTS should send Curriculum Vitae in confidence to:
Dr. Stephen Contro, Medical Director, MICHAEL REESE HEALTH PLAN, 2545 Martin Luther King Drive, Chicago 60616

an equal opportunity employer m/f/h

OBSTETRICIAN/ GYNECOLOGIST

The Department of Obstetrics and Gynecology of Tufts University School of Medicine and St. Margaret's Hospital for Women is seeking Generalists to join an expanding, high volume practice. Candidates should have an active interest in clinical practice, and resident and medical school education. Several positions are available. Interested candidates should contact:

Stephen Curry, M.D.
Professor and Chairman of the
Department of Obstetrics and Gynecology
Tufts University School of Medicine
and the New England Medical Center
750 Washington St.
Boston, MA 02111
Telephone: 617-956-6063

OBSTETRICIAN/ GYNECOLOGIST

Marshfield Clinic, a multispecialty private group practice of 250 physicians, is seeking an additional Obstetrician/Gynecologist to join its expanding 11 member OB/GYN Department. Large regional referral center practice with high risk program. Adjacent 524 bed acute care hospital includes a Level III Perinatal Center and a 24 bed Neonatal Unit. Teaching and research opportunities also exist. Send curriculum vitae to:

Mr.John P. Folz
Direct-Patient Services
1000 North Oak Avenue
Marshfield, WI 54449
or call collect at
(715) 387-5181

MarshfieldClinic

NORTH SUBURB OF CHICAGO

Position available with 45-person multi-specialty group practice. OB/Gyne needed to share responsibility for busy practice with two OB/Gynes. Competitive salary and benefits. Contact: Jose Kogan, M.D., Medical Director, North Suburban Clinic, Ltd., 4801 Church Street, Skokie, IL 60077.

KAISER PERMANENTE

Good People. Good Medicine.

Maternal-Fetal Medicine

BC/BE Perinatologist wanted to join another subspecialist in a large multispecialty HMO located in the San Francisco-Oakland Bay Area.

Responsibilities include clinical service in two tertiary referral centers with 6,000 deliveries/year; consultations in high risk patients, genetic testing, ultrasound, resident teaching, and perinatal outreach programs. CVS experience desirable.

Each institution with full NICU capabilities with total of six neonatologists. Oakland facility with approved residency program (12 residents), oncologist, endocrine-infertility subspecialists, Level II ultrasound capabilities and antenatal testing unit.

Excellent benefits including competitive salary, malpractice insurance, medical and dental coverage, vacation and sick leave, pension and retirement programs. University affiliation and clinical research available.

Please write or call, including your curriculum vitae and three references:

Victor Chin, M.D., FACOG
Chief, Department of Obstetrics & Gynecology
The Permanente Medical Group, Inc.
280 West MacArthur Blvd.
Oakland, CA 94611

OBSTETRICS AND GYNECOLOGY

honoring Robert Scully, M.D.

*Any Six Days — December 1-9, 1987 — Ch

Now, your only BOARD REVIEW just before Oral
is also an excellent update for surgeons and preview for Writ

OBJECTIVES
- Increase basic knowledge in obstetrics and gynecology
- Improve clinical skills in diagnosis and treatment
- Assist residents and fellows in organizing study
- Prepare board candidates to pass board examinations
- Provide practicing surgeons with a review and update

METHODS
- HOME STUDY MATERIALS with question based on previous examinations
- SEMINAR with projection slides and syllabus
- LABORATORY with microscopic slides
- PRACTICE EXAMS with oral and written parts

* Dec. 1-6 (live); Dec. 7-9 (Video replay of Dec. 1-3). Any consecutive six days will complete program.

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

21-and 28-day regimens

ORTHO-NOVUM 7/7/7

Tablets

ethindrone/ethinyl estradiol TRADEMARK

ite tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg drone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl ol. Each green tablet in 28-day regimen contains inert ingredients

TANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the and therefore should not be used as the basis for prescribing the product. This summary was prepared by from the complete prescribing information certain text, tables, and references. The physician should be hly familiar with the complete prescribing information before prescribing the product.

TIONS AND USAGE: PREVENTION OF PREGNANCY.

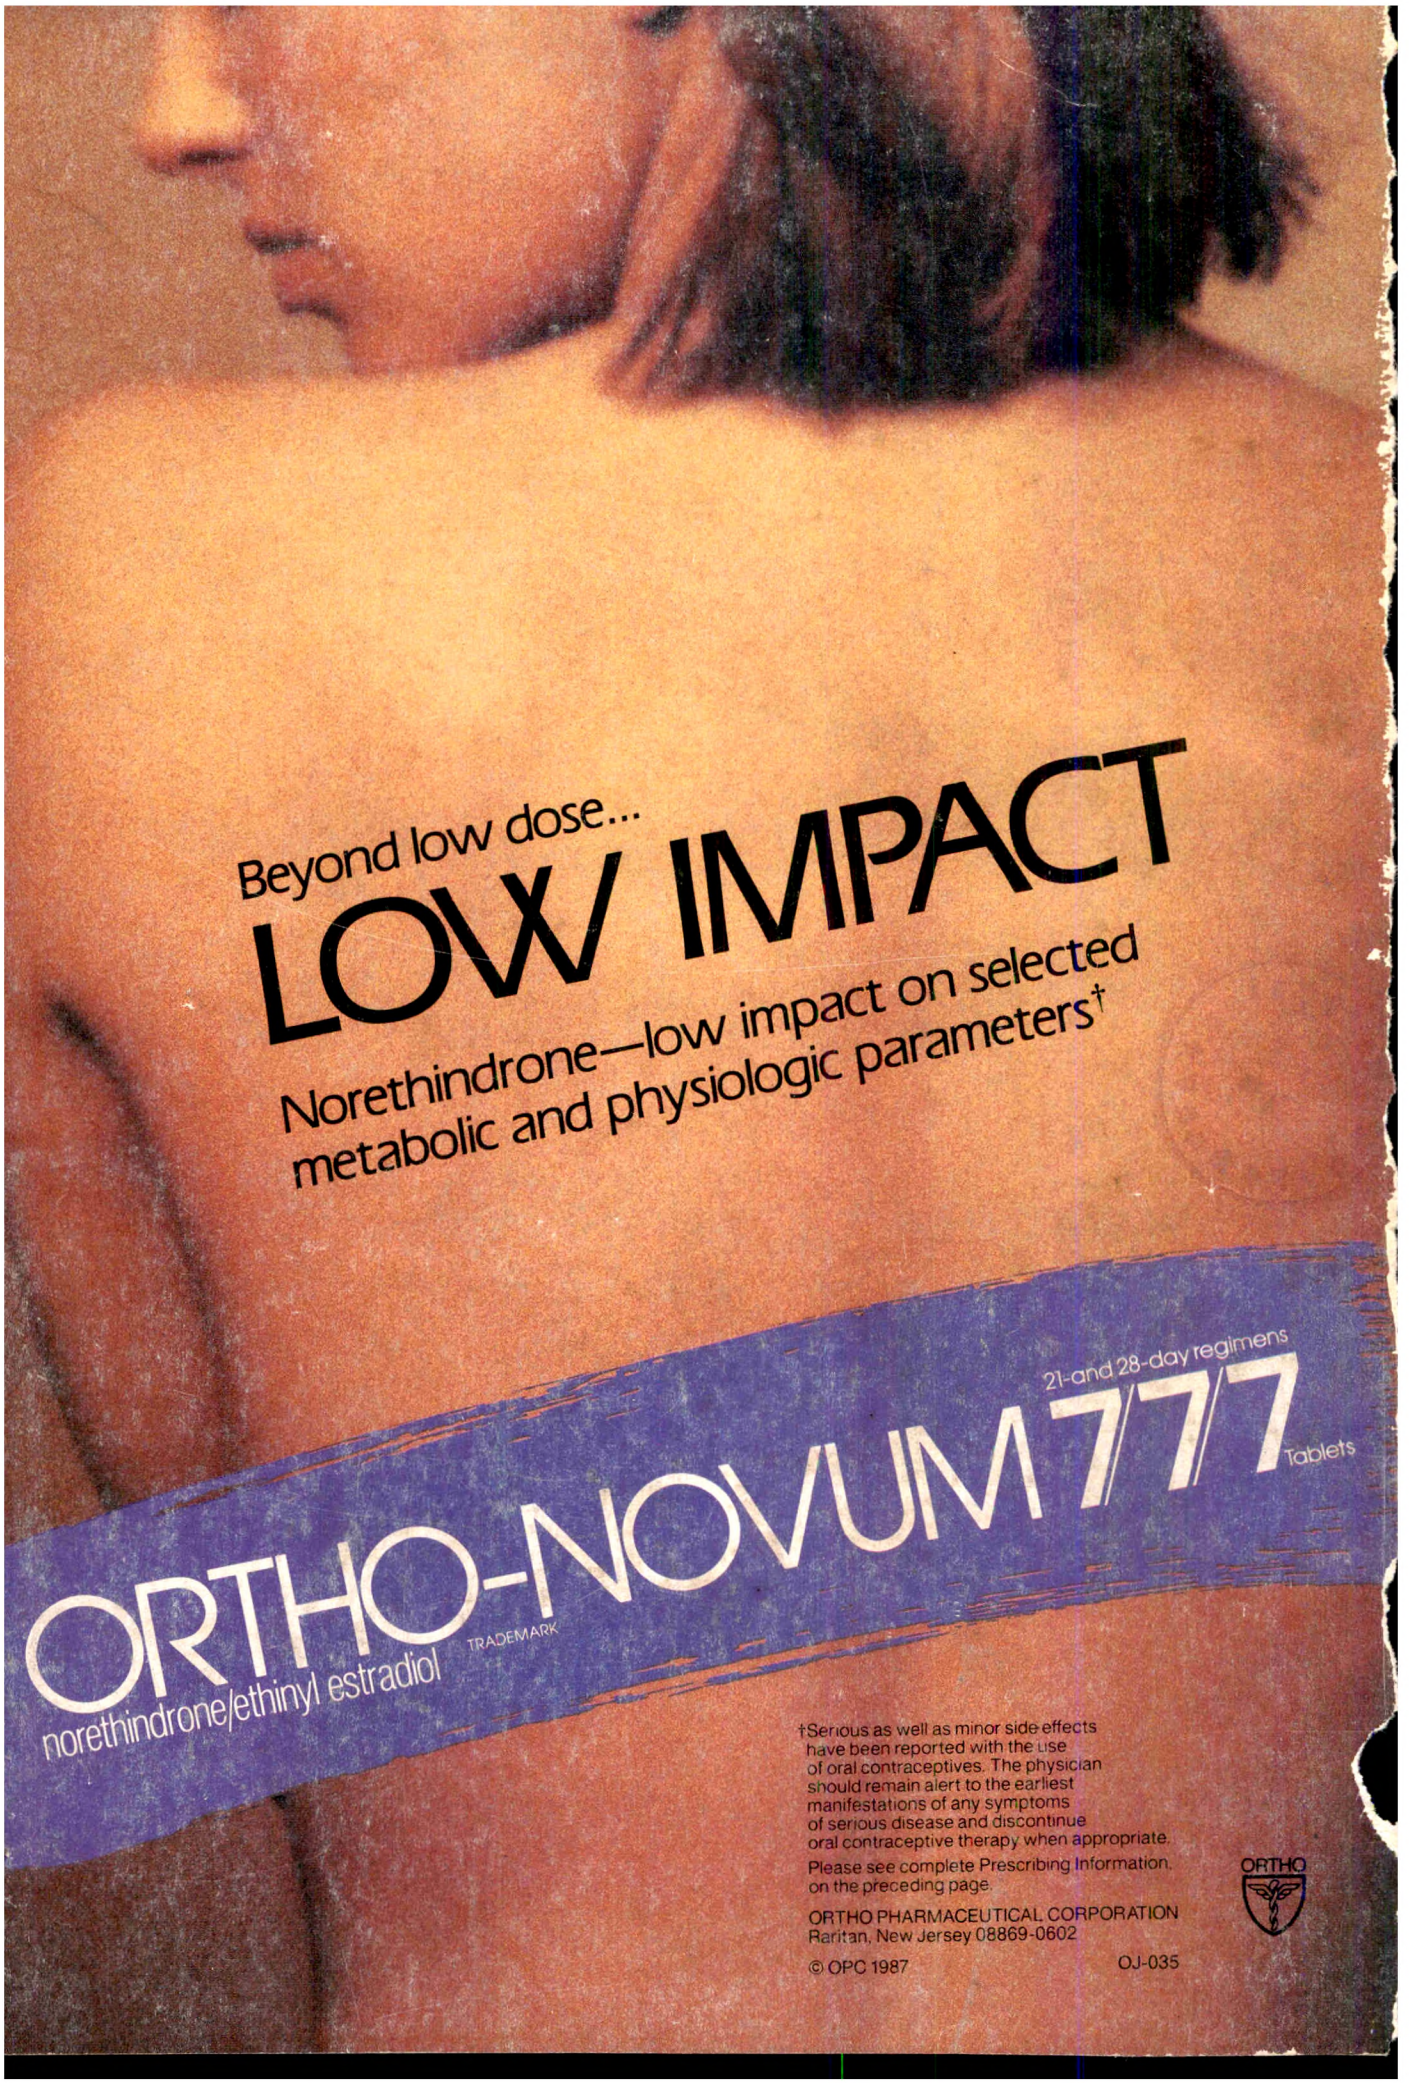
ELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive tion between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive prescribed for any given patient should be that product which contains the least amount of estrogen that is ble with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral ptives be started on preparations containing .05 mg or less of estrogen.

INDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. ophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic s. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or ed estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Oral contraceptive tablets may ital harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who nant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard etus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of ora ptives or other estrogen-containing products.

WARNINGS

ette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk ases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 s of age. Women who use oral contraceptives should be strongly advised not to smoke.
use of oral contraceptives is associated with increased risk of several serious conditions including mboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practi rs prescribing oral contraceptives should be familiar with the following information relating to these risks.

MBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and botic disease associated with the use of oral contraceptives is well established. Four principal studies in Great nd three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism ke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times ely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary m or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age.



OVASCULAR DISORDERS: In a collaborative American study of cerebrovascular disorders in women with and predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in s and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study ed in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study ed in the United States found that past use of oral contraceptives was associated with increased risk of nhoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial n associated with the use of oral contraceptives has been reported confirming a previously suspected ion. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of ng risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether ent was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive as estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers out a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold d risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor mining the importance of these relative risks, however, the baseline rates for various age groups must be given consideration. The importance of other predisposing conditions mentioned above in determining relative and risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a xtent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists g discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the

Risk of Dose: In an analysis of data derived from several national adverse reaction reporting systems, British tors concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher romboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful ological studies to determine the degree of thromboembolic risk associated with progestogen-only oral ptives have not been performed. Cases of thromboembolic disease have been reported in women using these s, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic s, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an dent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large tive study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was d to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000); the risk ncentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous ntermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for ore years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with us use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is ued. Another study published at the same time confirms a previously reported increase of mortality in pill users diovascular disease. The study concluded that the mortality associated with all methods of birth control is low w that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The en for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 s a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50

The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up bortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial n oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic s (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal sis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued tely. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral ptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type ed with an increased risk of thromboembolism or prolonged immobilization. 2. **OCULAR LESIONS.** There have orts of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral ptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete sion; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic ipeutic measures. 3. **CARCINOMA.** Long-term continuous administration of either natural or synthetic estrogen animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic gens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of rial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One n reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the rium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors ocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given; c ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no arketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of onal combination or progestogen-only oral contraceptives. Several studies have found no increases in breast women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive th documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral ptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of sed risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral ptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, te diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular ey elect to use oral contraceptives instead of other methods of contraception. 4. **HEPATIC TUMORS.** Benign denomas have been found to be associated with the use of oral contraceptives. One study showed that oral otive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. Cases of hepatocellular carcinoma, although rare, have been reported in women taking oral contraceptives. Retrospective studies conducted in the United States and Britain report an increased risk of hepatocellular carcinoma in oral contraceptive users, particularly with increased duration of use. 5. **USE IN OR IMMEDIATELY PRECEDING PREGNANCY. BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING.** The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7 fold increase in risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. **GALLBLADDER DISEASE.** Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. **CARBOHYDRATE AND LIPID METABOLIC EFFECTS.** A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. **ELEVATED BLOOD PRESSURE.** An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. **HEADACHE.** The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. **BLEEDING IRREGULARITIES.** Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. **ECTOPIC PREGNANCY.** Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. **BREAST FEEDING.** Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS. General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **DRUG/LABORATORY TEST INTERACTIONS:** The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS). Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

ORTHO PHARMACEUTICAL CORPORATION

ORTHO

Beyond low dose...
LOW IMPACT
Norethindrone—low impact on selected metabolic and physiologic parameters†
21- and 28-day regimens
ORTHO-NOVUM 7/7/7 Tablets
TRADEMARK
norethindrone/ethinyl estradiol
†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.
Please see complete Prescribing Information on the preceding page.
